Anemia

M. F. OXENHAM

Australian National University, Australia

Anemia is defined as “a condition in which the number of red blood cells (and consequently their oxygen carrying capacity) is insufficient to meet the body’s physiologic needs” (WHO 2011). The main congenital and/or acquired anemias discussed here include the hypochromic (and often microcytic), macrocytic, hemolytic, and aplastic anemias. Only a select range of common forms of these conditions are discussed, followed by a brief review of what are arguably skeletal signatures of some of the anemias. Note that the term erythrocyte or erythroid refers to red blood cells (RBC), while erythropoiesis describes the production of RBCs (in distinction to hemopoiesis, which refers to the production of all blood cells), and erythroid hyperplasia describes the excessive production of such cells or their precursors.

Hypochromic anemias

Iron deficiency anemia (IDA) is initially normocytic (normal cell size) and normochromic (normal cell color) with hypoproliferative bone marrow, but develops into a microcytic (small cell size), hypochromic (pale color) form (severe IDA) if untreated. Normal iron requirements differ by age and sex, with adult males requiring 0.5–1.0 mg/day compared to menstruating or pregnant females who require 1.0–3.0 mg/day or females aged 12–15 years who need 1.6–2.6 mg/day. Iron deficiency can be due to a range of causes including blood loss (e.g., parasitic infections, stomach ulcers, menarche, and trauma), physiological demands (e.g., prematurity, childhood growth, and pregnancy), malabsorption, and poor diet (Hoffbrand and Moss 2016). Erythroid hyperplasia (overproduction of RBC precursors) associated with

microcytic (small RBC) anemia is most commonly caused by iron deficiency. It is important to understand that in early to mild forms of IDA, erythroid hypoproliferation (underproduction) occurs, while in severe IDA, erythroid hyperplasia develops. Indeed, erythroid hyperplasia is seen in anemias involving RBC loss and destruction, and in conditions that include ineffective erythropoiesis. It is worth noting that two quite distinct anemic conditions (e.g., iron overloading diseases such as thalassemia and iron deficient conditions) are associated with suppression of hepcidin (the chief iron regulatory hormone) and concomitant increases in erythropoiesis. Hepcidin levels appear to be controlled by erythropoietic activity and not by iron levels in and of themselves. Similarly, soluble transferrin (a protein used in iron transport in the blood) levels in plasma are a measure of erythropoietic activity. Anemias associated with ineffective erythropoiesis (including IDA) display elevated levels of soluble transferrin receptors.

Anemia of chronic disorders (ACD) is associated with underlying chronic infectious (e.g., tuberculosis, osteomyelitis) and non-infectious (e.g., rheumatoid arthritis, sarcoidosis) diseases. ACD will generally only resolve with resolution of the underlying disease, and can be exacerbated by other conditions (e.g., iron, vitamin B₁₂, or folate deficiency). Factors contributing to the pathogenesis of ACD include a reduced level of iron recycling (during RBC turnover), due to increased serum hepcidin levels (in distinction to IDA), reduced RBC longevity, and a poor erythropoietin (EPO, a hormone controlling erythropoiesis) response to anemia. Note that erythroid hyperplasia is not seen in ACD (Hoffbrand and Moss 2016).

Other hypochromic anemias include sideroblastic anemia that results from a failure in heme (an iron compound associated with the transport of oxygen in RBCs) synthesis and can be associated with erythroid hyperplasia and ineffective erythropoiesis. Lead poisoning can lead to anemia, both hypochromic or hemolytic. Finally, iron refractory iron deficiency anemia (IRIDA)

is a relatively rare microcytic, hypochromic (with normal to elevated hepcidin levels) hereditary recessive anemia.

Macrocytic anemias

Megaloblastic anemias are characterized by hypercellular bone marrow and ineffective erythropoiesis (Hoffbrand 2015), and symptoms can include jaundice, glossitis (inflammation of the tongue), and stomatitis (inflammation of the mouth) (Hoffbrand and Moss 2016). These anemias are most commonly caused by vitamin B₁₂ or folate deficiencies that lead to defective DNA synthesis. B₁₂ is found in foods of animal origin and is not present in fruits or vegetables. B₁₂ deficiency is usually related to malabsorption, for which there are numerous causes, including fish tapeworm infections and the intestinal disease tropical sprue. Inadequate dietary intake also occurs, particularly among vegetarians who do not consume any animal products or individuals with very poor diets. Folate (pteroglutamic) acid is found in a range of foods, particularly vegetables and legumes. Folate and B₁₂ deficiencies can cause infertility, while folate deficiency in pregnant women is associated with elevated risks of neural tube defects in their children, while B₁₂ deficiency is associated with various neuropathies (Hoffbrand 2015).

Nonmegaloblastic macrocytic anemias have various causes, from liver disease and aplastic anemia through to pregnancy and smoking (Hoffbrand and Moss 2016).

Hemolytic anemias

Hemolytic anemias (HAs) are caused by an increased rate of RBC destruction (hemolysis) and there are both hereditary and acquired forms of the condition (Luzzatto 2015). Among the *hereditary forms*, severe congenital HA can lead to skeletal changes mediated by bone marrow activity. The two key categories of hereditary HA include those associated with membrane defects and those with defective red cell metabolism.

Membrane defects, caused by various mutations to the membrane proteins of RBCs, include hereditary spherocytosis (HS) and hereditary

elliptocytosis (HE). HS is common in northern Europeans and has autosomal dominant inheritance with variable expression that can manifest from infancy through to old age. It has a frequency of approximately 1 in 5,000. HE has similar clinical features to HS as well as a similar frequency. One form of HE, Southeast Asian ovalocytosis (where the RBCs take on an oval shape), has a frequency of 7 percent, thought to be due to a level of malarial protection afforded to the victim (Hoffbrand and Moss 2016; Luzzatto 2015).

Defective red cell metabolism includes a number of conditions, with glucose-6-phosphate dehydrogenase (G6PD) deficiency being the most important. Hundreds of variants occur and globally 400 million people are G6PD deficient. It is sex-linked (carried by females), with female heterozygotes enjoying falciparum (mosquito parasite) malaria resistance. G6PD deficiency is usually asymptomatic unless an individual is under oxidative stress (suffering from an overabundance of free radicals), which can be caused by a range of drugs, fava beans, or infections (Hoffbrand and Moss 2016; Luzzatto 2015).

Hereditary disorders of hemoglobin synthesis are associated with abnormal or reduced globin (protein chains) synthesis and they are the most common genetic defects globally, evolutionarily selected for due to their ability to protect the organism (or victim) from malarial infections.

Thalassemias, caused by poor globin (α or β chain) synthesis, are frequently seen in subtropical (β form, e.g., Mediterranean) and tropical (α form, e.g., sub-Saharan Africa, Southeast Asia, Middle East, India) regions. β thalassemia ranges from asymptomatic (carrier state) through to intermedia and major forms of the disease. β thalassemia major is transfusion dependent, that is, it causes death within the first or second decades in societies without access to modern medical treatment. It includes symptoms such as severe anemia, spleen and liver enlargement, bone expansion (marrow hyperplasia, skull bossing, hair on end X-rays of diploic bone), osteoporosis, infections, and liver disease. Thalassemia intermedia includes over 200 forms (based on genetic deletions) and can range from limited symptoms through to thalassemia major-type symptoms including, but not limited to, extramedullary erythropoiesis, gall stones, osteoporosis, and bone deformity (Hoffbrand and Moss 2016).

Sickle cell anemia is caused by inheritance of the sickle β -globin gene, with the resulting sickled RBCs causing vessel blockages and localized organ tissue death (i.e., infarcts). Up to 30 percent of Africans have the carrier state, which provides protection from malaria. In its homozygous form, symptoms range from mild to extreme (including severe hemolytic anemia and crises), where crises can include: (1) bone infarcts (especially shoulders, hips, vertebrae, hands, and feet); (2) organ infarcts (e.g., acute sickle chest syndrome, the most common form of death in adults and children); (3) aplastic anemia; (4) hemolytic crises; and (5) lower leg ulcers. Sickle cell can combine with other hemoglobin disorders such as thalassemia (Hoffbrand and Moss 2016).

Aplastic anemias

Aplastic (hypoplastic) anemia is essentially pancytopenia (reduction in all blood cell lines) due to bone marrow hypoplasia and includes primary and secondary (associated with drugs, chemicals, viruses, and transfusions) forms. A primary, congenital, example is *Fanconi's anemia*, often causing skeletal defects and growth retardation, including microcephaly and radius/thumb aplasia. The most common form of aplastic anemia is *idiopathic acquired aplastic anemia*, where an autoimmune response affects hemopoietic (blood cell forming) tissue (Hoffbrand and Moss 2016).

Congenital dyserythropoietic anemias (CDAs) are defined by ineffective erythropoiesis and erythroblast multinuclearity. CDAs are also refractory anemias (i.e., they can only be treated with blood transfusions and are not associated with any other primary disease process) and can cause expansion of the bone marrow (Hoffbrand and Moss 2016).

Skeletal signatures of anemia

In theory, any form of anemia that is associated with a period of erythroid hyperplasia and/or ineffective erythropoiesis has the potential to cause bone marrow expansion, which may manifest skeletally as an expanded medullary space and cortical bone thinning. It is worth noting

that about 25 percent of all active marrow in infants is concentrated in the cranium and all infant bones display 100 percent marrow cellularity, as compared to ca. 7 percent of total active marrow occurring in adult crania (Cristy 1981). As such, children should presumably be at a much greater risk, in comparison to adults, of cranio-facial skeletal changes when subject to a range of acquired and congenital anemias.

While skeletal changes associated with some hereditary hemolytic anemias (e.g., diploic expansion, cranial bossing, and maxillary hyperplasia in β -thalassemia and bone infarcts in sickle cell anemia) are clear, such bony changes are seldom reported in the clinical literature for other forms of anemia. Notwithstanding, early reports have noted cranial and postcranial skeletal changes associated with chronic IDA that are consistent with the erythroid hyperplasia and/or ineffective erythropoiesis seen in the chronic form of this disease. Indeed, any form of anemia with associated erythroid hyperplasia and/or ineffective erythropoiesis (severe iron, B_{12} , and folate deficiency, for instance) could, in theory, lead to these types of skeletal changes.

In the bioarchaeological and palaeopathological literature, two cranial lesions, porotic hyperostosis (PH) and cribra orbitalia (CO), are often attributed to IDA (see Oxenham and Cavill 2010). While there is clinical evidence suggesting that some of the anemias could lead to the type of lesions that characterize PH, there is currently no clear clinical evidence that CO is a bony response to any of the anemias. It is, however, theoretically plausible that diploic expansion and cortical bone thinning in the orbital roof could be caused by erythroid hyperplasia and/or ineffective erythropoiesis in response to IDA, some of the HAs, and megaloblastic anemias in infants and children. Nonetheless, a single common etiological pathway linking PH and CO has yet to be found. PH aside, a range of other conditions have been theoretically or clinically linked to the various forms of expression of CO, including pseudopathologies, subperiosteal inflammation due to a range of infections (Wapler, Crubezy, and Schultz 2004), scurvy (Brickley and Ives 2006), and orbital hematomas of various aetiologies (Ma'luf et al. 2002). In paleopathological cases, the differential diagnosis for these types of cranial (including orbital) lesions will include a wide

range of conditions, invariably including IDA, HA, and megaloblastic anemia. Nonetheless, given current issues in clearly identifying the underlying etiology of PH and CO, it is perhaps best to simply treat these lesions as skeletal signatures of nonspecific physiological stress unless additional overwhelming evidence suggests one etiological pathway over another.

Bioarchaeology

LORI E. WRIGHT

Texas A&M University, USA

Today, the field of bioarchaeology is generally understood to encompass a broad range of methodologies that extract biological and cultural information from archaeological human skeletal remains. Although the term was first applied in the broader context of any biological data recovered from archaeological sites, such as paleobotanical remains (see PALEOETHNOBOTANY), faunal remains (see ZOOARCHAEOLOGY), and other indicators of paleoenvironment (Clark 1972), this usage has given way to a narrower focus on human skeletons and mortuary contexts as a source of data. The term “bioarchaeology” was first applied to human remains in this sense by Buikstra (1977). Thereafter, the field emphasized the bridging of biological and cultural data obtained from human remains, especially as applied in a populational perspective. Thereby, bioarchaeology was distinguished from the traditional descriptive osteological report typically published as an appendix to an archaeological site report and from “osteobiography” (Saul 1972) that emphasized individual life histories. This new discipline was situated in the more evolutionary context of population biology that laid the framework for the “New Physical Anthropology” (Washburn 1951) and was also allied with the growth of processual archaeology. Thus, one can consider bioarchaeology to be an endeavor that bridges between physical (biological) anthropology and archaeology.

Despite focusing on human remains as a source of biological data, bioarchaeology emphasizes the cultural context of human remains and archaeological theory building as sources of research hypotheses. Hence, bioarchaeological research designs of the later twentieth century, and, in particular, North America and the United Kingdom, emphasized the use of skeletal data to address cultural questions about

major demographic transitions, such as the adoption of agriculture (Cohen and Armelagos 1984), the arrival of Europeans in the Americas (Larsen and Milner 1994), and the emergence of social complexity (Steckel and Rose 2002). The new millennium has seen a return to questions of individual life histories and biocultural aspects of identity, and has embraced studies of paleomobility and population genetics.

Osteology and paleodemography

Bioarchaeology is rooted in the study of the human skeleton, called osteology (see OSTEOLGY), and begins with the excavation of human remains in archaeological sites (see BURIAL EXCAVATION and COMMINGLED HUMAN REMAINS) and an attempt to understand the mortuary or funerary context (see MORTUARY ANALYSIS) in which they were encountered. In addition to evaluating the depositional history of the remains, human osteologists attempt to identify the age at death and skeletal sex of the remains they examine.

For remains that are not skeletally mature, age is typically estimated by reference to dental development (see ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION), growth of limb bones (see ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH), or maturation of epiphyses (see ESTIMATING SUBADULT AGE: EPIPHYSEAL UNION). Ongoing research in human skeletal biology and growth and development has led to a variety of new methods and standards for such age assessment in recent years. For remains of adults, the age-related deterioration of the skeleton occurs more variably; however, research continues to refine methods to assess age using the cranial sutures, pubic symphyses (see ESTIMATING ADULT AGE: PUBIC MORPHOLOGY), and auricular surfaces of the ilium (see ESTIMATING ADULT AGE: AURICULAR SURFACE MORPHOLOGY), among other features. Recent publications emphasize Bayesian statistical treatment of skeletal age characteristics to obtain probabilistic estimates of age at death (see ESTIMATING ADULT AGE: TRANSITION ANALYSIS).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0061

Identification of sex from skeletal remains is usually limited to adult skeletons or those nearing skeletal maturity. Dimorphic features of the cranium and pelvis (see ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY) are most useful for sexing adult skeletons, although metric dimensions of the postcranial skeleton (see ESTIMATING SKELETAL SEX: METRICS) are also useful if appropriate population-specific reference data are available. Although some skeletal features may be dimorphic in children, considerable interpopulation variation and conflicting study results lead most workers to shy away from making such assessments. However, sex assessment using ancient DNA is quite promising (Faerman et al. 1998) (see CHROMOSOMAL DNA).

Age and sex assignments form the basic data used in paleodemography (see PALEODEMOGRAPHY), especially life table (see LIFE TABLE ANALYSIS) and hazards analyses (see PALEODEMOGRAPHY AND HAZARDS ANALYSIS). Together with archaeological indicators of population growth and decline, paleodemography gives considerable insight into the population dynamics of past societies through time, and the consequences of human adaptation to environmental contexts.

Biodistance

Human remains provide the possibility of understanding the evolutionary relationships between ancient societies and peoples. Such “biodistance” studies (see BIOLOGICAL DISTANCE) attempt to measure the extent of biological separation, and conversely the shared ancestry and intermixture among ancient skeletal remains across both geographic and chronological space. Until the last few decades, such work emphasized the size and shape of the cranium (see CRANIOMETRY) and teeth (see DENTAL METRICS) as well as morphological traits of the skeleton and dentition (see DISCRETE TRAITS). Both approaches have helped flesh out population dynamics in prehistoric North America and Europe. Recent advances in the recovery, authentication, and interpretation of genetic material from ancient skeletons (see GENETICS: ANCIENT) and teeth have begun to provide more detailed understanding

of human diversity than was possible from early studies of mitochondrial DNA alone (see DNA: NEXT GENERATION SEQUENCING). New methods for sequencing DNA, called “next generation sequencing” (see DNA: MITOCHONDRIAL), now permit rapid sequencing of many fragments of DNA from a single sample, which ultimately allows reconstruction of partial genomes (see GENOMICS: ANCIENT) and more detailed biodistance analysis of ancient remains.

Paleomobility

Geochemical approaches to document population movement are an important new complement to paleodemographic and biodistance research. Ratios of the stable isotopes of strontium ($^{87}\text{Sr}/^{86}\text{Sr}$) (see MOBILITY AND STRONTIUM ISOTOPES) and lead ($^{207}\text{Pb}/^{204}\text{Pb}$, $^{208}\text{Pb}/^{204}\text{Pb}$, $^{206}\text{Pb}/^{204}\text{Pb}$) (see MOBILITY AND LEAD ISOTOPES) are incorporated into bone mineral in proportion to their abundance in foods. Since these ratios reflect the geological origins of soils on which plant foods have grown, they preserve a geological signal in the bone or tooth mineral. Similarly, stable oxygen isotopes reflect the geographic and climatological origin of water imbibed, and are an important complement to the above methods. The stable isotope ratios of oxygen ($\delta^{18}\text{O}$) (see MOBILITY AND OXYGEN ISOTOPES) provide an important additional source of paleomobility data, but are affected by nursing and cultural practices, so are somewhat more challenging to interpret than the heavy Sr and Pb isotopes.

Paleodietary reconstruction

Direct measures of food consumption through chemical analyses of human remains have flourished since the 1980s. An early focus on the relative concentrations of the alkaline earth elements (strontium, barium, and calcium) in bone mineral (see DIET AND TRACE ELEMENTS) has given way to measurement of stable isotope ratios in bone collagen and tooth and bone mineral. Elemental analysis has been put aside largely due to concerns about both the effects of diagenesis

(elemental exchange with the burial environment (see *DIAGENESIS OF BONE*)) on alkaline earth ratios and uncertainty about interpretation of observed patterning. Diagenesis can also be a problem for isotope ratios; however, isotope signatures are somewhat more straightforward to interpret. Stable carbon isotope ratios ($\delta^{13}\text{C}$) (see *DIET AND CARBON ISOTOPES*) in bone collagen and skeletal mineral reflect the intake of foods with disparate content of the two stable isotopes of carbon, ^{13}C and ^{12}C . Such $\delta^{13}\text{C}$ ratios vary among plants due to enzymes used in varied photosynthetic pathways. This approach has been especially helpful in the Americas where maize (*Zea mays*) stands out as nearly the only major ancient cultigen with a distinctive $\delta^{13}\text{C}$ ratio. Stable nitrogen isotope ratios ($\delta^{15}\text{N}$) of animal tissues are enriched in ^{15}N compared to the proteins consumed, and therefore measure sources of dietary protein (see *DIET AND NITROGEN ISOTOPES*). A newer addition to the isotopic toolkit, the stable isotopic ratios of sulfur in bone collagen ($\delta^{34}\text{S}$), is useful to isolate proteins from aquatic sources in the diet (see *DIET AND SULFUR ISOTOPES*). Together, these methods have enabled a much more precise understanding of food intake by individual participants of the past, and of ancient paleoecology.

Infant feeding and childhood growth

Paleodietary research that compares carbon and nitrogen isotope signals in skeletons of differing ages at death has shed light on the diets of infants and children and developed into the study of breastfeeding and weaning in the past. This approach has been extended to include the use of oxygen isotopes (see *INFANT FEEDING*) in dental tissues, which form in infancy and childhood, allowing researchers to track water intake, nursing, and dietary changes during childhood within an individual.

The consequences of infant feeding and nutritional practices on health through the lifespan have been a longstanding interest in bioarchaeology (see *INFANT FEEDING*). Infant health has been studied both by examining the remains of infants and through the study of dental enamel hypoplasias, which are defects formed in tooth

enamel due to growth arrest during childhood (see *DENTAL DEVELOPMENT*). Completed skeletal stature (see *STATURE ESTIMATION*) provides a long-term index of growth achievement. Together, these approaches shed light on the processes of morbidity and mortality that form the basis of demographic change in ancient and modern societies.

Paleopathology

Evidence of ill health during life is often recorded in the skeleton; however, it is important to underscore that most morbid conditions leave little mark on the skeleton (see *PALEOPATHOLOGY*). Although some conditions, such as certain bone cancers (see *CANCER*) and congenital conditions, leave distinctive skeletal features (see *CONGENITAL CONDITIONS*), most nutritional (see *ANEMIA* and *MALNUTRITION*) and metabolic (see *METABOLIC DISEASE*) conditions leave much less obvious signs in the skeleton and most infectious conditions (see *INFECTIOUS DISEASE*) cause non-specific bony reactions. Careful differential diagnosis (see *DIFFERENTIAL DIAGNOSIS*) of skeletal anomalies is necessary to identify the health challenges affecting past communities. In the unusual case where soft tissues are preserved through mummification, imaging studies may aid diagnosis (see *IMAGING IN HUMAN REMAINS*), and parasites may also be preserved in or on the body (see *PARASITOLOGY*). Dental caries, abscesses, and calculus deposits can provide indications about oral health (see *ORAL HEALTH*) and dietary practices.

Behavior

Paleopathology may also shed light on past physical activity and behavior. For instance, bones fracture in characteristic ways depending on the stresses they are placed under (see *TRAUMA*), and their occurrence is unequal among archaeological skeletal populations. Similarly, bony joints degenerate with age and repetitive motion (see *DEGENERATIVE JOINT DISEASE*). Together with study of muscle attachment sites that remodel when placed under functional pressures (see *MUSCULOSKELETAL STRESS MARKERS*),

bone architecture and cross-sectional geometry (see CROSS-SECTIONAL GEOMETRY) reflect behavior and activity to a degree, and may shed light on differing lifeways at the population or subpopulation level.

There has also been considerable interest in cultural modifications of the human skeleton since the earliest archaeological work, and intentional cranial shaping (see CRANIAL SHAPING) and esthetic decoration of the teeth (see DENTAL DECORATION) continue to be frequent subjects of bioarchaeological work. Recently, these have been key components of archaeological theory building that emphasizes exploration of ancient ideas of embodiment (see EMBODIMENT) and the symbolic role of the body in cultural discourses of the past.

Ethics

Bioarchaeology too must grapple with ethical questions concerning how the study of human remains intersects with culturally appropriate treatment of the deceased, often requiring considerable efforts at collaboration and negotiation with descendant communities. Often, repatriation of remains may be required after study, a compromise that makes clear the need for detailed and standardized data recording of osteological, chemical, and genetic data such that these would be available for future comparative study.

Biological Distance

CHRISTOPHER M. STOJANOWSKI

Arizona State University, USA

Biological distance analysis, or biodistance, uses phenotypic variation as a genetic proxy to reconstruct evolutionary mechanisms and patterns of biological diversity in past human populations. As such, the approach generally shares the same goals as anthropological genetics, with an emphasis on intraspecific (within species) microevolutionary interpretations (see *GENETICS: ANCIENT*). Biological distance uses heritable phenotypes, that is, metric and nonmetric variation of the cranium and dentition, as the basis for evolutionary inferences. At the broadest scale, patterns of global phenotypic variation help identify the process of modern human emergence and migration throughout the Old and New Worlds. For example, biodistance has contributed to our understanding of the peopling of North and South America, the peopling of Polynesia, and the repopulation of the Green Sahara. At the smallest scale, biological distance analysis can be used to determine whether two individuals buried together were biological kin or not. A key feature of biological distance analysis is scalability, from the micro to the global (Buikstra, Frankenberg, and Konigsberg 1990), which requires careful consideration of data collection protocols.

Four classes of biodistance data are recognized: craniometric, dental metric (odontometric), cranial nonmetric, and dental morphological. Each class of biological distance data has its strengths and weaknesses. Craniometric data analysis has the deepest history within the field, a history steeped in notions of skull collecting, race science, and typology. While modern craniometric analyses avoid such criticisms, the patina still remains and it is important to recognize that dental anthropology and cranial nonmetric anatomy do not share the same historical trajectories.

Metric data are recorded using established protocols, increasingly with intensive three-dimensional imaging and data capture techniques

(see *IMAGING IN HUMAN REMAINS*). Craniometric data collection is based on well-known osteometric landmarks (see *CRANIOMETRY*). Odontometric data typically comprise length and breadth measurements of the tooth crown and neck (see *DENTAL METRICS*). Analyses of metric data are simpler due to the ratio scale nature of these variables; however, theoretical concerns about the importance of size and shape should be considered (see *MULTIVARIATE ANALYSIS*). Ratio scale data are amenable to standard multivariate statistical analysis, as well as the more theoretically grounded R matrix analysis (Relethford 2007).

Cranial nonmetric data are anatomical variants of the skull that include variation in cranial ossicles (extra bones in the sutures), the number and formation of foramina, and hyperstotic (excess bone) and hypostotic (underdeveloped bone) skeletal features (see *DISCRETE TRAITS*). Dental morphology refers to anatomical variation of the tooth crown and roots, including extra cusps and enamel projections near the crown margins and neck. Both cranial nonmetric and dental morphological traits are recorded in a discontinuous scale that includes nominal and ordinal data types. As such, these traits are often dichotomized into binary variables for the purposes of frequency estimation. The discontinuous scale, however, complicates statistical treatments and until recently such data were not amenable to more theoretically grounded approaches such as R matrix analysis.

The basic assumption of biodistance analysis is that two closely related individuals are more phenotypically similar to each other than two unrelated individuals. By extension, two populations that exchange mates regularly are more similar to each other than two isolated populations, and the same is true of two populations that share a more recent common ancestor. Providing justification for these assumptions has been difficult. Many appeal to published studies of inheritance patterns for the different classes of biodistance data, despite the difficulty of interpreting what these estimates actually mean. Studies comparing the concordance of phenotypic and genetic data at multiple scales

(von Cramon-Taubadel and Weaver 2009), from the global to the inter individual, do support the validity of these basic assumptions. However, further work is needed to understand the genetic coding of phenotypic variation and the sources of environmental noise that result from how the body develops within a framework that includes both genetic and nongenetic mechanisms.

A number of archaeological questions can be answered with biodistance analyses. At the scale of regional inference, analyses of phenotypic variation can be used to reconstruct patterns of migration and gene flow, ancestor–descendant relationships, population replacement events, population boundaries, and mortuary variability related to cemetery use practices (Larsen 2015). Intracemetery approaches also address a number of questions relevant to archaeology (Stojanowski and Schillaci 2006). Spatial analysis of phenotypic variation (see SPATIAL ANALYSIS) can reveal how a cemetery was organized and provide evidence of the existence of biological lineages, which can inform fine-grained studies of health and status. Comparison of male and female phenotypic variation speaks to postmarital residence practices, which have implications for understanding ancient social organization. More recent approaches have incorporated biological distance analysis into studies of ethnicity and social identity by emphasizing the relevance of marriage and mate exchange within the broader social world of humans.

Despite being an imperfect proxy for genetic sequence data, biodistance offers a number of benefits, including its nondestructive and relatively cost- and time-efficient nature, its ability to sample the populations of interest and model temporal changes directly, its statistically

tractable sample sizes, and its universal applicability regardless of host DNA preservation or contamination.

Burial Excavation

BARRA O'DONNABHAIN

University College Cork, Republic of Ireland

When viewed through both time and space, human groups have demonstrated a vast diversity in their approaches to the disposal of their dead. While the dead end up buried in the earth in many societies, there are many other ways of disposing of bodies—such as exposure or disposal at sea—that do not leave archaeological traces. Burial is a form of disposal that involves remains being placed in the ground and covered over but there is significant diversity here too as burials can take many forms: inhumations; cremations; primary deposits; secondary deposits; ossuaries; mummies; bog bodies. Burials can provide a direct and tangible link to individual actors in the past and have always had a high profile both in the discipline and at the level of popular culture. This high profile is partly due to the fact that while death is a biological event, it is also a cultural experience that can provoke profound responses. Despite the fact that mortuary contexts link biological and cultural domains in this way, burial archaeology has had a chequered history in the discipline. Like antiquarian studies before it, the culture-history approach of the first half of the twentieth century had a strong focus on elite burials. Artifacts and architecture tended to be privileged in this approach. If they were curated, human remains retrieved from these contexts were used extensively in typological studies of racial difference. While these approaches had declined by the time of the development of the processual approach to archaeology, mortuary contexts were the focus of important theoretical advances linking funerary behaviors to their social contexts (e.g., Brown 1971). While the study of elite burials continued, particularly in relation to theorizing about social status, the move to processualist perspectives led to a democratization of burial archaeology. The development of interpretative approaches

since the 1980s has seen the further broadening of theoretical scope and one of the outcomes of this has been what Nilsson Stutz and Tarlow (2013) have characterized as a recentring of mortuary contexts in archaeology. This is in no small part due to the interdisciplinary approach championed by bioarchaeology, a subdiscipline that emerged in the late 1970s as part of the “New Archaeology.” Bioarchaeology has played an important role in promoting integrative approaches to graves and their contents (Rakita 2014), and archaeology as a whole has moved from relating cemeteries to parameters such as territoriality or the control of resources to a broader view that includes seeing these locations as reflections of past cosmologies.

Excavation

While theoretical landscapes and recording methods have changed considerably in recent decades, the excavation of a burial is still done in ways that would have been familiar to early twentieth-century archaeologists. Burial excavation is a fascinating process that creates an intimate triangular link between people who lived in the past, unborn generations of the future, and the excavator. This is because once a burial has been fully excavated, the process cannot be repeated as excavation is destructive. Excavators therefore have an ethical obligation to make sure that their recording system is comprehensive, systematic, and permanent. This ensures that future generations will be able to examine their work in fine detail and reevaluate interpretations if necessary.

The process of excavation begins with the identification of a grave cut. This is the outline of a pit dug in the past and backfilled once the remains, burnt or unburnt, had been placed in the ground. Most excavations proceed stratigraphically which means that buried features are usually excavated in a sequence that is the reverse of their deposition. The grave backfill is removed first, taking care to identify and preserve the edges of the

DOI: 10.1002/9781119188230.saseas0068

grave cut. Human remains will be encountered usually at the base of the grave fill and should be left in situ until all of the bones are exposed and recorded. While trowels are usually used to excavate down to a burial, they are not the ideal tool for the excavation of skeletal remains. Smaller tools such as a mason's leaf should be used. Soil samples may be taken during the excavation process for analyses of factors such as the presence of intestinal parasites, where the earth lying immediately over the sacrum of a skeleton is collected along with a control sample taken from behind the skull. Care should be taken that any artifacts present in the burial should also be left in situ so that their precise location and associations can be recorded.

Recording burials

The burial must be comprehensively recorded prior to lifting the remains and this usually involves creating paper and photographic records along with detailed, scaled drawings. Standardized forms are often used for each skeleton as well as for each context uncovered during the excavation. Photographs are taken with a scale, an arrow indicating where north is located and a storyboard with information about the burial such as site name, date, and burial number. There have been important methodological advances in how archaeological burials are recorded. The process has been revolutionized by technologies such as photogrammetry and 3D scanning. While the latter involves equipment that not all projects can access, all that is required in the field for photogrammetry is a good camera and if proper protocols are followed, hand drawings are not needed. These methods have the added benefit of reducing the time between the uncovering of burial contents and their conservation. Three-dimensional models of burials can be scaled and georeferenced for placing them in geographic information systems (GIS). This allows for the digital reconstruction of stratigraphy as well as the production of highly accurate site plans. Similarly, 3D scanning of artifacts and human remains allows for the creation of digital museums that can facilitate greater access to data while reducing the deterioration of the

originals. One important contribution that relies on very precise recording in the field is the approach developed in France, *L'Antropologie "de Terrain"* (Duday et al. 1990). This has the goal of distinguishing between cultural behaviors and taphonomic changes in the disposition of remains.

Lifting burials

Once a burial has been recorded, the excavator gently loosens the remains from the soil. Remains are not prised out of the ground but gently freed from the earth surrounding them and placed in clearly labelled bags. These should be prepared prior to lifting the remains and each bag should be labeled with indelible pen with the site name, year of excavation, burial number, and the skeletal elements contained in the bag. The main parts of the skeleton should be bagged separately, distinguishing between each side. The remains are then transferred from the field to the lab where they are washed, dried, and rebagged in a similar way before being boxed, ideally in a sturdy plastic crate, for long-term curation. Poorly preserved or delicate remains should be dried, wrapped in acid-free paper and then bagged and boxed.

Changing views of burials

Early twentieth-century archaeologists tended to pay more attention to burial architecture than to buried bodies. In turn, the processual approach to grave architecture was dominated by formal analysis. More recent approaches to burial-related monumentality stress meaning as well as form. Similarly while artifacts may also have been privileged over other elements in burials in the past, recent approaches have been more holistic and insights regarding materiality have framed much of the discussion regarding grave goods. Rather than being viewed as static signifiers of factors such as status or gender, grave goods have been recast as mediators of social relations and are understood in a more dynamic manner that stresses the agency of objects. Explorations of funerary practices in archaeology have also been transformed by insights from social theory with

a stress on the contextual and dynamic nature of ritual.

Approaches to archaeological burials have also been transformed by explicit theorizing of the body. Burial archaeology has made a significant contribution to the dynamic theoretical perspectives that have emerged around the archaeological body. Phenomenological approaches played an important role in transforming perspectives of the body in the archaeological imagination. These placed an emphasis on the physicality of the body and its interaction with the material world. While undeniably biological and physical, the archaeological body is also understood as something formed by cultural processes: the body is molded by a lifetime of performance of culturally-constructed roles (Sofaer 2006). These performances occur in architectural settings and in relation to material objects, a perspective that brings together elements of burial archaeology that were previously considered independently. Incorporating bioarchaeological data has also transformed the manner in which we look at archaeological bodies. The manner in which bioarchaeological research tended to analyze individual skeletons in order to pool data to discuss populations has prefigured narratives of the individual versus the collective body. Integrative approaches to mortuary patterning of age, sex, and pathology (a two-way process that has influenced bioarchaeological praxis) have opened discussions on issues such as how we conceptualize health and ill-health in the past, care, disability, social deviance, childhood, and social age. There has been significant discussion of gender and a rejection of simplistic equations with particular grave goods, arguing instead for approaches that look critically at theories of human action. Contemporary arguments for nonbinary views present interesting challenges for understanding the performance and experience of gender in past societies and demand critical reflection. Equally, new insights from techniques such as DNA and stable isotopes challenge us to consider the relationship between bodies and objects in new ways. Both of these techniques have yielded data on issues such as the movement of people in the past and cultural practices such as matrilocality and patrilocality. Isotopes have also yielded significant data on dietary practices. The very fact that archaeologists engage with graves from the

past shows that death is not the end: memory of the dead is important in many societies. From the “working dead” (Laqueur 2015) to the political lives of dead bodies (Verdery 1999), the dead can remain a powerful force among the living. Through a combination of all of these elements, the archaeology of mortuary contexts can provide insights into lived experiences, identities, and power in past societies.

Traditional burial archaeology has had a big influence on forensic archaeology. This influence is not a one-way process with non-forensic archaeological approaches benefiting from work carried out for judicial purposes. Projects such as the Body Farm (Bass and Jefferson 2004) have informed approaches in the retrieval of non-recent remains while forensic work on mass graves, along with the emergence of the archaeology of the contemporary, has paved the way for the recently articulated Holocaust archaeologies.

These interesting changes and the increased recognition of the importance of mortuary contexts have occurred against a backdrop of the increased politicization of archaeological burials. Resistance to the excavation of graves, as well as to the long-term curation of artifacts and particularly the human remains contained therein, emerged partly as a backlash against cavalier attitudes by archaeologists and others in the past but also as a result of the increasing empowerment of descent groups in the post-World War II era of decolonization. In 1989, the World Archaeological Congress sponsored an “inter-congress” at Vermillion, South Dakota around the theme of “archaeological ethics and the treatment of the dead.” The resulting Vermillion Accord on Human Remains (WAC 1989) placed the wishes of the dead, where they can be ascertained, along with those of local and descent communities on a par with the scientific research value of the remains. This code influenced the development of policies in a number of world areas, not least in the United States where the Native American Graves Protection and Repatriation Act (NAG-PRA) was enacted in 1990. While high-profile controversies have continued over some sites and assemblages, these initiatives have fostered debate around issues of ethics and respect—for the living and the dead—in many world areas.

Cancer

TONY WALDRON

University College of London, UK

Cancer is the generic name given to those tumors that have the propensity to spread from their site of origin to other parts of the body, and for this reason they are referred to as malignant. Benign tumors, by contrast, do not spread but remain in their parent tissue. Tumor spread may be local or distant, affecting almost any organ of the body, including the skeleton. The original tumor is known as the primary tumor, while those that spread are referred to as secondary tumors or metastases. There are two principal types of cancer: carcinomas—tumors that arise in epithelial tissues such as those that line the inner or outer surfaces of the body; and sarcomas—tumors that arise from the supporting tissues of the body; *stricto sensu* they arise in cells derived from mesenchyme. Carcinomas are by far the most common type.

Cancer is ubiquitous among animals and is concomitant with multicellularity, since with each cell division there is a possibility that errors arise in the DNA that in some cases may lead to malignant change. Cancer cells are not subject to the normal controls on cell division and on programmed cell death; hence these mechanisms do not limit the growth and spread of cancer cells.

There is no reason to suppose that humans (and other animals) have not been subject to malignant changes from the earliest times. Relatively few cases appear in the paleopathological literature, because cancer is, *par excellence*, a disease of the elderly. Cancer is rare below the age of 60, but thereafter its incidence rises steeply with increasing age, so that by the age of 80 almost everyone has a tumor somewhere. It is not likely that, until recently, many individuals lived into the ages at which cancer is common. The age- and sex-specific prevalences of malignant disease in the past were probably similar to those of today (Waldron 1996),

although it is likely that the distribution of tumor types was different owing to differing habits and exposures to putative carcinogens in the environment.

Perhaps a more significant reason for the rarity of tumors in the archaeological record is what one might call the problem of attrition. This can best be appreciated from an example. In the first annual report of the registrar general for England and Wales, almost 356,000 deaths were recorded for the year July 1, 1837–June 30, 1838. This number for one single year is far greater than the total number of human remains that have been examined from this country, which lessens very considerably the chances of finding any remains with evidence of cancer. And then, when one considers how nonrandom the process of recovering human remains is and that a relatively high proportion of them are incomplete, lacking precisely those elements that are most likely to be affected by secondary tumors, then it is a wonder that any evidence of cancer is found at all.

Secondary tumors of bone

Secondary bone tumors are many times more common than primary bone tumors and, although almost any primary tumor may spread to the skeleton, some show a much greater predilection to do so than others. The primary tumors that most often affect bone are those arising in the thyroid, kidney, breast, lung, and prostate. Thyroid and kidney tumors are the ones most likely to invade the skeleton but, since they are not nearly as common as breast, lung, or prostate cancer, secondaries from the last three sites make up the greatest proportion of skeletal tumors. Spread to the skeleton tends to take place via the lymphatic or venous systems, but the various regions of the skeleton are by no means equally likely to be affected. Thus secondary bone tumors tend to be found in the skull, spinal column, pelvis, and proximal femur. Secondary bone tumors are rarely found in the bones of the arm, hand, lower leg, and foot.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0071

Secondary tumors typically produce either lytic or sclerotic lesions—and sometimes a mixture of the two. Those that are lytic secrete cytokines such as RANKL, which stimulate the production and activity of osteoclasts, to the point of causing holes in bones. The most dramatic effects of secondary tumors are often seen as multiple holes of varying sizes in the skull. The lesions have ragged, undercut edges with no signs of healing, and in life would have been filled with tissue from the primary site. The radiography of affected bones will almost always show a number of radiolucent areas that represent lesions within the substance of the bones that are not visible to the naked eye, as well as lesions that have destroyed the cortex.

There is no way in which secondary tumors of the breast or lung (or indeed of any other site) can be differentiated in the skeleton; the diagnosis must be based on probability. Thus lesions found in a male are much more likely to be from a lung primary, for, although breast cancer does occur in men, it is much less frequent than lung cancer. Conversely, lesions found in a female are more likely to be from a breast primary, since breast cancer is more common in women than lung cancer. It is never possible to be dogmatic in a particular case, however. There is also an alternative diagnosis that needs to be borne in mind, and that is of multiple myeloma. This is a malignant disease that arises from plasma cells in the bone marrow, and it, too, causes holes in bones through the production of cytokines that stimulate osteoclasts. The lesions appear in exactly the same places as lytic secondaries from other primaries and, in practice, it is impossible to differentiate between them on morphological grounds. Some authors claim that the lesions produced by myeloma cells are more regular in size than those caused by breast or lung secondaries. Myeloma cells produce an abnormal immunoglobulin, called myeloma protein, in great quantities in the blood and in urine, where it can readily be detected. Myeloma protein might survive death and burial and has been detected at least once in a skeleton (Cattaneo et al. 1994); its presence, of course, will confirm a diagnosis, but its absence is not helpful one way or the other.

Tumors of the prostate act to stimulate osteoblasts, thereby causing sclerotic secondaries through the production of cytokines, together with the production of quantities of immature

bone. Bones containing prostatic secondaries will appear normal but may be slightly heavier than usual. In the spine, for example, some of the lower thoracic or lumbar vertebrae may seem heavier than their neighbors and radiography may show dense new bone within them. These may be difficult to differentiate from Paget's disease. A rare form of prostatic cancer has been reported in the paleopathological literature simply because it forms periosteal new bone in abundance throughout the skeleton (Waldron 1997). It is likely that more cases of prostatic cancer would be detected if the skeletons of elderly males were routinely X-rayed.

Primary bone tumors

Primary bone tumors are exceptionally rare, being slightly more common in males than in females. In the present-day population of the United Kingdom, their incidence is approximately 8.5 per million in males and 6 per million in females. Three types account for virtually all primary bone tumors: osteosarcoma, chondrosarcoma, and Ewing's sarcoma. Osteosarcoma and Ewing's sarcoma are tumors that predominantly affect children and young adults, their peak incidence occurring between the ages of 5 and 20. For osteosarcoma, there is also a much smaller peak in old age in a minority of individuals with Paget's disease who develop malignant change in some of their affected bones. Chondrosarcoma is rare in the young, but its incidence increases steadily with advancing age. Osteosarcoma is the most common type of primary bone tumor (some 47 percent of the total) and is followed by chondrosarcoma (33 percent); Ewing's sarcoma accounts for the remaining 20 percent.

Each type of tumor tends to have a different skeletal distribution. Most osteosarcomas occur in the long bones of the leg, especially around the knee joint. The remainder may be found in almost any other bone. These rapidly formed masses occur on the external surface of the affected bones and often have a characteristic X-ray appearance, described as a "sunburst." Chondrosarcomas, by contrast, favor the pelvis and the axial skeleton and develop within the bone substance. Their presence may be suggested by subperiosteal

deposits enlarging affected bones. Ewing's sarcomas develop as lesions within the long bones, including the clavicle, with consequent localized periosteal expansion on the affected bones. Plain radiography or computerized tomography (CT) scanning of unusual lesions on bones should be undertaken wherever possible and may aid in diagnosis. Even with the help of an experienced skeletal radiologist, however, firm diagnosis may be impossible; modern-day pathologists rely on histological evidence to come to a conclusion, but, of course, such evidence is not available to the paleopathologist, who works with skeletal remains.

Cancer in mummies

Mummies provide the paleopathologist with a much higher chance of making a positive diagnosis of a primary tumor, although the internal organs are not always present, or not always well preserved. The problem of attrition is even greater with mummies, but there are cases in the literature that should nevertheless encourage the continued search for evidence (David and Zimmerman 2010).

The diagnosis of cancer in human remains

In the vast majority of cases, paleopathologists will be dealing with skeletal rather than mummified remains, in which case the diagnosis of cancer is one of the probabilities rather than a certainty. There are many diseases that may give rise to lytic lesions in bones, but fortunately most of them are unusual or rare (Waldron 2009). It is important, however, to have some knowledge of the prevalence of those conditions that may mimic cancer in the skeleton, so that a realistic assessment may be made of their likely appearance. However trite, always bear in mind that common things occur commonly and, conversely, rarities are seldom seen.

There are almost no ancillary investigations that will help in making a diagnosis. Radiography is sometimes instructive, particularly with those tumors that may be contained within bone, of course, but it proves to be disappointing more

often than not. It is possible that, some time in the future, we will be able to extract molecular or genetic markers of cancer, but this is not likely to be an option for the paleopathologist in the near term.

Chromosomal DNA

ANNA E. LINDERHOLM
Texas A&M University, USA

What are chromosomes?

DNA consists of two chains of base pairs wound into a double helix. A base pair is a pair of complementary bases, consisting of a purine in one strand linked by hydrogen bonds to a pyrimidine in the other. Cytosine always pairs with guanine, and adenine with thymine (in DNA, or uracil in RNA). Some 3 percent of the DNA consists of genes that confer a trait; the rest is so-called junk DNA without clear purpose (some claim that it acts like scaffolds to the genes). Nuclear DNA, or chromosomal DNA, includes part or all of the genetic material (genome) of an organism. Gametes are an organism's reproductive cells. Female gametes are called egg cells, and male gametes are called sperm. Gametes are haploid cells, meaning that each cell carries only one copy of each chromosome. Chromosomal DNA is found inside the nucleus of a cell, and its quantity varies widely between different organisms. Humans have 46 chromosomes, of which 22 pairs are called autosomes, which look the same in both males and females. The 23rd pair, the sex chromosomes, differs between males and females (the Y-chromosome and the X-chromosome, respectively). One set of chromosomes for each pair comes from a person's mother, and the other set of chromosomes comes from the father. This inheritance pattern is very important and is in stark contrast to the way mitochondrial DNA is inherited, which is solely from the mother, and the Y-chromosome is inherited, which is solely from the father. Although most of the DNA is packaged in chromosomes within the nucleus, the mitochondria also have a small amount of their own DNA. The mitochondria are structures within the cells suspended in the cytoplasm that convert the energy from food into a form that cells can use as energy (i.e., adenosine

triphosphate, ATP). When scientists speak about sequencing whole genomes, they are speaking about the chromosomal DNA, as the mitochondrial DNA (mtDNA) is only a small part of the human genome (3.2 billion base pairs vs. 16,500 base pairs) (see DNA: MITOCHONDRIAL).

The history of ancient DNA

At the beginning of ancient DNA research (see GENETICS: ANCIENT), only mtDNA was used due to its abundance (thousands of copies) and ease of replication (it is very short). In 1983, Mullis developed a technique that mimics the cell's own DNA replication process; he called it polymerase chain reaction (PCR). By using this technique, a single copy or a few copies of a segment of DNA can be amplified, generating thousands to millions of copies of a particular DNA sequence. The first real use of chromosomal DNA in archaeology came in 1996 when the first chromosomal DNA was used to determine the sex of several archaeological individuals based on the amelogenin gene. There is a difference of 12 base pairs (bp) between the gene on the Y-chromosome versus the gene on the X-chromosome (Stoneking 1996). This technique has since been used regularly throughout the 1990s and into the 2000s, especially when osteologists cannot tell whether skeletal remains are female or male (see OSTEOLOGY). Even though researchers had shown that nuclear DNA could be extracted and analyzed, nothing much changed during the next 10 years, and mitochondrial DNA was predominantly used; what little chromosomal DNA sequences could be analyzed were often disputed. The main issue was initially the authenticity and/or origin of the ancient chromosomal DNA. Many sequences were too damaged or short and thus were hard to identify. Adding to this, scientists were using human archaeological remains, and this made it difficult to separate modern contamination from authentic ancient DNA. This contamination could come from chemical reagents, the archaeologists/

osteologists/geneticists themselves, or from the burial environment of the remains.

Genetic markers

In 2005, a number of studies reported the successful recovery of ancient chromosomal DNA sequences that allowed the characterization of genetic loci directly involved in phenotypic traits of extinct taxa. For the first time, the field of ancient DNA could show what extinct species might have looked like. This was groundbreaking and soon led to a flurry of research targeting easy genetic loci that involved phenotypic traits, such as skin and hair color (e.g., *MC1R*, a receptor that plays an important role in pigmentation), and adaptive traits, such as lactose intolerance. It is true that the great majority of phenotypic characteristics are complex traits, complicating the identification of the genes underlying their expression, but for some we now know the underlying mutations due to genome-wide association studies.

Point mutations or SNPs

A single nucleotide polymorphism (SNP) is a DNA sequence variation occurring commonly within a population (e.g., 1 percent) in which a single nucleotide (A, T, C, or G) differs between members of a biological species or paired chromosomes. Before the introduction of next-generation sequencing (NGS), SNPs were predominantly used for looking for both changes in the chromosomal DNA and phenotypic expressions. Next-generation sequencing changed all of this, making it possible to look at whole genomes or thousands of SNPs. All of this new data has made it possible to study admixture, population origins, and the like (see *DNA: NEXT GENERATION SEQUENCING*).

The melanocortin 1 receptor (MC1R)

One of the key proteins involved in regulating mammalian skin and hair color is *MC1R*. The receptor is primarily located on the surface of melanocytes, which are specialized cells that produce a pigment called melanin. The skin or hair

color can change based on a single point mutation. This SNP has a different location for different mammals, making it very useful for a wide range of studies. Since 2006, it has been steadily used in archaeological studies to determine the coat colors of mammoths, cattle, horses, dogs, pigs, as well as the hair color of the Neanderthals and ancient humans (Linderholm and Larson 2013).

Lactose tolerance

Normally we lose our ability to digest the milk sugar lactose by the time we stop breastfeeding. However, the ability to consume milk as an adult occurs at high frequencies in present-day populations, coinciding with the practice of dairying and cattle rearing. Genetic frequency maps show that northern Europe has the highest frequency of lactose tolerance. Sweden has the highest incidence, with over 70 percent lactose tolerance. This is an adaptive trait that has undergone an enormous positive selection, possibly driven by gene-cultural co-evolution. The -13910*T allele associated with this trait (in Europeans) seems to have been subjected to strong selection over a relatively short period of time. It was first detected in ancient population samples in 2009, and since then has been used to track the introduction of dairying across Europe (Malmström et al. 2010).

Admixture

One of the most pervasive debates in archaeology was whether or not the Neanderthals and modern humans interacted with each other. Early data from mtDNA did not show this to be the case. However, the only way to truly investigate admixture is by looking at chromosomal DNA (to detect DNA signals from both parents). Initially, long or even shorter fragments of chromosomal DNA from ancient materials seemed to be much harder to obtain than first thought. So SNPs were first targeted in order to be able to use chromosomal DNA for archaeological admixture analysis. By using SNPs, shorter fragments of chromosomal DNA could be utilized. By using this approach, genome-wide SNP data (that is, SNPs from across the whole genome) from both contemporary populations and extinct hominins were generated

to examine potential admixture events in prehistory. The datasets obtained strongly support a single dispersal of modern humans from Africa, followed by two archaic admixture events: one with Neanderthals somewhere outside Africa, and a second with Denisovans in Asia. By using chromosomal DNA, the long-lasting debate has been dissolved; we now have solid evidence for an admixture between not only modern humans and Neanderthals, but also with Denisovans.

Chromosomal DNA and validity

For the most part, the authenticity of the results from chromosomal DNA was still an issue. To resolve this, a group of scientists published a paper in 2006 about assessing the fidelity of nuclear ancient DNA, comparing it with mtDNA; they found that they behaved very similarly, despite great differences in cellular copy numbers (one nucleus vs. thousands of mitochondria) (Binladen et al. 2006). That is, the postmortem damage patterns are the same regardless of DNA source; the authors showed the existence of miscoding lesion damage in both mtDNA and chromosomal DNA, resulting in insertion of erroneous bases during amplification. This type of damage pattern can now be used as an authentication method when using NGS. However, care still needs to be taken when working with allelic variation and the confidence in single nucleotide polymorphism identifications.

Genomes and next-generation technology

Whole genomes are a great source of information, due to the recombination that occurs in each generation, so one whole genome could potentially represent a whole population. A genome is an organism's complete set of DNA, including all of its genes. Each genome contains all of the information needed to build and maintain that organism. Two technological innovations made the study of ancient whole genomes possible, and both happened early in 2000: next-generation sequencing and DNA hybridization enrichment. Together, these resulted in multifold increases in

both the quantity and the quality of ancient chromosomal DNA sequence data. The sequence data output went from 0.7× coverage (mammoth) in 2008 to more than 50× coverage (Neanderthal) in 2014. Coverage (or depth) in DNA sequencing is the number of reads that covers a given nucleotide in the reconstructed sequence. The time depth for DNA retrieval has also been pushed backwards by using this technique; the oldest to date is a horse dated to approximately 560–780 thousand years before present (Orlando et al. 2013) (see GENOMICS: ANCIENT).

The future

The last couple of years have seen an explosion in whole genome assemblies. DNA sequence assembly is a process through which short DNA sequence fragments (called reads) are merged into a longer DNA sequence in an attempt to reconstruct the original DNA sequence. We now have hundreds of them (from humans, animals, and other organisms), spanning both time and space. The possibility of what we can study seems endless; we can identify and track rapid evolutionary changes, such as the evolution and spread of pathogens and the genetic responses of hosts, or slower events such as the genetics behind domestication and climatic adaptation. New statistical methods and modeling programs used to analyze the genetic material are developing swiftly, and the importance of paleogenomics for investigating evolutionary processes during the last million years is likely to increase considerably in the future.

Commingled Human Remains

ANNA J. OSTERHOLTZ

Mississippi State University, USA

Commingled human remains can be defined as the mixing of the elements of multiple individuals into a single archaeological or forensic context. This can occur through both natural and cultural mechanisms, and usually both will have an effect on the way archaeological assemblages can be examined. Both archaeological and forensic assemblages are discussed, with an emphasis on how the creation of the assemblage will affect possible analyses. Assemblages can be broken into three different categories: (1) long-term usage (those used for multiple depositional episodes, typically across generations); (2) episodic usage (those used for single depositional events resulting from the deposition of multiple individuals at a single time in a single deposit); and (3) lab commingling (unintentional commingling of individuals that occurs during analysis and storage). Finally, a short discussion of analytic methodology is included. Important to keep in mind with any analysis of commingled remains is that there is no *right* way to analyze a commingled assemblage; methodology will depend on the research questions of the analyst.

Long-term usage assemblages are typically the result of primary and secondary interments from community groups. Primary interments are the initial interments of the body, usually occurring shortly after death. These may be disturbed or altered to produce a secondary interment. An example of secondary interments may include bundled bones collected from primary interments. Assemblages resulting from accretional primary burials will have different archaeological representativeness than those resulting from the periodic gathering of primary burials into a secondary assemblage. Primary assemblages will be based on the placement of primary burials into a collective tomb or grave with the addition of

more primary burials on top of previous burials. This type of assemblage will have an adequate representation of smaller elements, though through time these smaller elements may filter to the bottom of the assemblage due to normal shifting of elements and decomposition of the primary burial. Assemblages resulting from the gathering of skeletal elements for deposition in a secondary burial will have fewer small elements since these are more difficult to recover. Elements of newer burials are added to the mass containing older elements. Because of the attritional aspects of this type of assemblage, smaller elements such as hand and foot bones may filter to the bottom of the assemblage or may be poorly represented as they might not have been collected from primary burials. Often, a mixture of primary and secondary burials will be present in a long-term use assemblage, such as that typified by Tell Abraq, a Bronze Age ossuary dating to 2200–2100 BCE in the United Arab Emirates. The representativeness of hand and foot bones was used as a proxy measurement of primary versus secondary deposition for this assemblage. It was determined to have approximately 30 percent of the expected number of hand phalanges, suggesting primary depositions of individuals that were allowed to decompose naturally before being moved to the edges of the tomb to make room for additional burials and burial bundles.

Episodic usage assemblages can be best thought of as assemblages resulting from mass burials. These may be the result of plague, sacrifice, or warfare, any activity that will result in the death of multiple individuals at a single time. They are, therefore, episodic in nature, versus a longer term accretional assemblage like that discussed previously. Characteristics of these assemblages may include minimal commingling, depending on the natural processes present. If significant earth pressure or earth movement is not present, little or no commingling may be present. If they are buried in a location close to the surface or with heavy bioturbation (disturbance by living organisms such as insects as well as scavengers), commingling may be severe. Element representation is typically consistent

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0100

with the demography of the burial population. Demography will also reflect processes leading to the creation of the assemblage: for example, epidemics are expected to affect the very young and very old more than young adults. In the case of epidemic commingled burials, fears of contamination are also a factor in the creation of the assemblage. For example, burials associated with epidemic outbreaks may only be given rudimentary burial rites—they may be placed in a communal grave without coffins or other signs of social rank such as grave goods. This may result in increased commingling when combined with taphonomic factors such as earth movement and bioturbation. Epidemic burials may also be hurried and make use of existing pits or unused structures such as mine shafts.

Warfare burials may also form episodic burials. Examples of this include the Battle of Little Bighorn/Greasy Grass (nineteenth-century America) and the Battle of Towton (fifteenth-century Yorkshire). Battlefield assemblages may have increased levels of commingling due to intentional postmortem mutilation or processing of the remains (e.g., mutilation of commanders and trophy taking). Demography of such assemblages will also vary depending on combatants. It is expected that assemblages resulting from warfare will contain more adult and adolescent males than females. Raiding activity may also result in episodic burials that show commingling, however. The taking of women and children as captives doesn't always lead to their incorporation into new communities. Brooks (2016) details an eighteenth-century massacre of the village of Awat'ovi (in modern-day Arizona) in which the women and children were led away from the village toward other villages after the mass killing of most of the males of the community. At some point, a decision was made to kill the captives and their commingled remains were recovered in nearby Polacca Wash in the twentieth century. Raiding may also occur when young males were not present, so demography of mass graves resulting from this type of raiding would be unlikely to have those individuals represented in significant numbers.

Assemblages resulting from ethnic cleansing and genocide would also fall under the umbrella of episodic assemblages. The United Nations General Assembly codified genocide as a legal

concept as the intentional destruction of a specific group based on national, ethnic, racial, or religious affiliation. The demography of such a mass grave may be key to an identification of a genocidal assemblage, since it is expected to contain all individuals of the selected group. These assemblages may contain perimortem injuries and postmortem processing. These assemblages are thoroughly explored in Adams and Byrd (2014).

Commingled assemblages from the American Southwest provide a useful example. Assemblages exhibiting extreme processing (Kuckelman, Lightfoot, and Martin 2000) are episodic commingled assemblages. These include the case studies present in Turner and Turner's (1999) *Man Corn* as well as the Sacred Ridge assemblage (Osterholtz 2013). These assemblages have signs of defleshing and dismemberment as well as extensive commingling of individuals. These assemblages have been interpreted by some as indicative of cannibalism (e.g., White 1992), terrorism (e.g., Turner and Turner 1999), witchcraft executions (e.g., Darling 1998), and politically motivated massacres with performative overtones. Episodic assemblages may also be the result of postmortem processing of the dead as part of a mortuary program, cooptation of ritual space and land tenure (see case studies in Osterholtz, Bausation, and Martin 2014). Manipulation of the dead may be important for the construction of social status and identity, regardless of how it occurs.

The final type of commingling occurs in the laboratory or field during analysis or curation. While this is unintentional, lab commingling can complicate analysis for numerous reasons, primarily the loss of excavation information and context. When commingling occurs in the course of the creation of an archaeological deposit, such as that at Tell Abraq or Sacred Ridge (a Southwestern assemblage dating to approximately AD 800), the mapping of the deposit can create location data that can be added to the bony data to understand how the deposition occurred and allow for more thorough interpretation of the assemblage. When this contextual information is lost through lab commingling, analysis can be severely limited. The use of excavation photos and notebooks can be useful in determining the degree of lab commingling and the untangling of lab commingled deposits.

Methodologies for the analysis of commingled remains varies based on the research questions of the researcher. Due to the nature of the assemblages, baseline data must first be determined, and then this can be used for secondary analyses. Baseline data, such as the minimum number of individuals (MNI) and the demography of the assemblage (sex and age at death distribution), can be difficult to determine, but are useful in the overall interpretation of the assemblage. It is through the identification of the demography of some assemblages that epidemic mass graves can be identified, for instance. Determining MNI is a complicated process, particularly in assemblages with significant fragmentation, such as those exhibiting extreme processing. The author argues for a feature-based approach for the determination of MNI, where individual skeletal features are identified for each fragment and tallied to determine MNI. This method of MNI determination will give an overall MNI based solely on the duplication of features; the MNI should be then examined based on the demography. It is therefore important to choose features for the determination of MNI that are sexually dimorphic and will give at least some indication of age at death of the individual. For Sacred Ridge, over 50 features were recorded for the entire skeleton. In particular, over 20 features on the skull were recorded. Other methods for the determination of MNI are essentially also based on the duplication of elements. Hermann, Devlin and Stanton (2014), for instance, have used a 3D scanning technique that allows for the overlay of individual fragments to determine how many elements are present by stacking the 3D images to look for overlapping elements. This method does not rely on the identification of features, and while requiring significant computer resources and time, provides a very accurate determination of MNI.

Congenital Conditions

SCOTT E. BURNETT

Eckerd College, USA

D. TROY CASE

NC State University, USA

The term “congenital” refers to physical traits, usually pathological, that are already present at birth. This category captures a wide spectrum of developmental conditions, including syndromes such as Down syndrome, and major malformations such as cleft palate and polydactyly. Loosely defined, it also includes developmental variants, minor anomalies that may become more apparent with age. Etiologically, congenital conditions are diverse, resulting from genetic mutations, exposure to teratogens, and maternal health factors during pregnancy. As a result, the interpretive value of congenital conditions in anthropological contexts varies according to the type of condition and the factors responsible for its occurrence. Although congenital conditions may affect any system of the body, here we focus primarily on those syndromes, major malformations, and minor variants that are manifest in the skeleton and are therefore identifiable in archaeological contexts.

Most syndromes and major malformations are thought to be quite rare in the archaeological record when compared to their frequencies in modern clinical studies. One explanation might be infanticide of the malformed, resulting from cultural ideas about the nature and viability of individuals with specific conditions. In other cases, premature mortality, differential burial, or issues of skeletal preservation might be to blame for the low frequencies. Whatever the cause, most syndromes and birth defects identified in the archaeological record are discovered incidentally.

Several dwarfing syndromes have been identified in archaeological contexts, including achondroplasia, the most common form of dwarfism today. Achondroplasia is a bone

growth disorder characterized by disproportionate dwarfing of the limbs, primarily affecting the upper arms and legs, relative to the trunk. Achondroplastic dwarfs also exhibit a bulbous forehead, midface hypoplasia, bowed legs, and hand anomalies. Approximately 1 in 40,000 people are affected today, most due to spontaneous mutations to the FGFR3 gene, but the condition may also be inherited from an affected parent. Though diagnosis of a specific dwarfing condition out of 100+ known possibilities can be difficult, achondroplasia has been proposed to explain most archaeological cases. Dozens of affected skeletons are known worldwide, and numerous artistic depictions of dwarfs have been identified in ancient Egypt and Greece (Dasen 2013). In Egypt, artistic and textual evidence indicates that some dwarfs held positions of religious and administrative significance, including oversight of the royal wardrobe and pets. The potential for dwarfs achieving high status in society is supported by the interment of several near the pyramids at Giza and Saqqara, and at the site of Abydos.

Trisomy 21, commonly known as Down syndrome, typically occurs due to nondisjunction of the 21st chromosome. Affected individuals exhibit nonskeletal manifestations such as intellectual disability and developmental delay, along with a suite of possible skeletal characteristics including a short broad head, depressed midface, small jaw, and shortened digits. In addition, dental indicators may include missing teeth, tooth transposition, or dental crowding. Trisomy 21 is the most commonly occurring genetic syndrome in humans, with a rate of approximately 1 in 700 births in the United States. Despite this, extremely few cases of trisomy 21 have been identified in the archaeological record. Reasons for the paucity of affected individuals from archaeological contexts may include infanticide, shortened lifespan, and a lower incidence of Down syndrome in antiquity. The frequency of trisomy 21 is influenced by maternal age, and ranges from about 1 in 2,000 for 20-year-old mothers to 1 in a 100 by age 40. If fewer mothers lived into their 40s in the past, then the probability of Down syndrome would also be reduced.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0111

While all of these reasons may account, in part, for the lack of skeletons with trisomy 21 in the archaeological record, the discrepancy between the modern incidence of dwarfing conditions and trisomy 21, relative to their identification in the archaeological record, is still surprising. We should not assume that infanticide, as a culture-dependent practice, or the lower average age of mothers would fully explain the lack of individuals with trisomy 21 in antiquity. After all, most affected individuals today are born to younger mothers, simply because younger individuals are more likely to reproduce. Furthermore, women in past societies may not have had effective means to control conception at older ages. Indeed, the discrepancy between the number of dwarfs and the number of trisomy 21 cases identified in ancient skeletal material probably says more about osteological training than about people from the past. It would be difficult to overlook the dramatically short height and unusual limb robusticity found in achondroplasia, for example, while the physical manifestations of trisomy 21 are subtle and occur, albeit in lower frequencies, in the population at large.

Major congenital malformations occur sporadically in the archaeological record. They may include cranial defects such as cleft lip/palate, or malformations of the limbs or trunk. In some cases, these conditions have clear detrimental impacts on the likelihood of survival. Individuals with cleft lip/palate, for example, often have difficulty breastfeeding, reducing their likelihood of thriving without assistive measures. Despite this risk, dozens of archaeological cases of cleft palate are known dating from as early as the Neolithic. Of course, folk interpretations of congenital malformations vary by society and time period. In Medieval Europe, cleft lip was often attributed to maternal impression, whereby the sights, emotions, and experiences of a pregnant woman could affect the form of her infant. By this way of thinking, a woman who gave birth to an infant with cleft lip was believed to have thought about or seen a hare, or a similarly affected individual during pregnancy, hence the derogatory term “harelip.”

In some severe congenital malformations, affected individuals may exhibit shortened lifespans. Two such life-threatening conditions are anencephaly and spina bifida, which are related neural tube defects affecting the brain and/or

spine that can result from both genetic and environmental factors, including low maternal folate (vitamin B9) levels during pregnancy. Anencephalic individuals have incomplete formation of the brain and skull and few survive more than a few days after birth. Perhaps partly due to taphonomic and cultural biases that may inhibit their recovery and identification, anencephalic individuals are extremely rare in the archaeological record (Dudar 2010). Discovery of an anencephalic individual in a collection of mummified baboons from ancient Egypt suggests that the individual may not have been considered fully human.

Spina bifida, a malformation characterized by failure of the neural tube to fully close, may involve hydrocephaly, mental deficiencies, and partial paralysis in cases of protrusion of the spinal cord. The degree of mobility impairment and the impact on life expectancy varies depending on which part of the spine is affected. An adolescent with spina bifida of the lower spine from the archaeological site of Windover in Florida also displays evidence of lower limb infection, disuse atrophy, and loss of the right foot that together indicate sensory deficits, ulceration, and the loss of mobility seen in this 7,500-year-old skeleton (Dickel and Doran 1989).

Polydactyly, characterized by extra fingers or toes, is another major malformation that is reported much less often archaeologically than its modern frequency might predict. Most studies suggest rates in various populations between 1 in 100 and 1 in 1,000 births. The reasons for infrequent reporting probably relate to a number of factors, the most important being that extra digits are usually considerably underdeveloped in most individuals and hard to recognize in isolation. Therefore, polydactyly is difficult to identify in archaeological skeletons unless the relevant bones are undisturbed during recovery. Among the limited number of reported polydactyly cases from antiquity, the Southwestern United States seems to be the region with the greatest number (Case et al. 2006). Widespread depictions of both hands and feet with sixth digits also occur in Southwest rock art and Mesoamerican iconography. Because polydactyly has both a genetic and a nutritional component, either (or both) might explain the higher frequency in the Southwest.

Another condition that may affect the foot is talipes equinovarus, commonly known as clubfoot. Individuals with talipes equinovarus display a downward-pointing heel and inward-facing sole affecting both the bones and associated soft tissues of the foot. While the occurrence of clubfoot varies by population, it is seen on average in 1 in 750 births, with males affected more often than females. Both genetic and environmental factors appear to be associated with idiopathic clubfoot. A bilateral case was recently reported from the Mayan site of Tikal in Guatemala (Wright 2011). However, despite the skeletal involvement, relatively few cases have been reported archaeologically, given modern frequencies of the condition.

Minor congenital variants are much more common and are frequently asymptomatic. Many, including tarsal coalition and vertebral malsegmentation, are unlikely to have been recognized in life. Both of these conditions occur due to failure of bones to separate during embryonic and fetal development, resulting in the union of adjacent bones via fibrocartilaginous or osseous tissue. These conditions may occur in isolation or as part of a syndrome. Malsegmentation of the second and third cervical vertebrae, for example, is unlikely to be noticed in a living individual, but some affected individuals with the condition have Klippel–Feil syndrome and also display a webbed neck, congenital elevation of the shoulders, and an additional bone between the spine and scapula.

Tarsal coalition, a congenital malsegmentation anomaly between adjacent bones of the ankle and foot, is asymptomatic in most affected individuals. However, increasing evidence of population variation in its occurrence can be useful in anthropological contexts. Recent analyses suggest the existence of population-specific patterns of expression that may be useful in examining population movements. For example, known cases of tarsal coalition among ancient Native Americans correlate with patterns seen in East Asian samples, indicating that patterns seen in native New World populations may originate from Old World Asian ancestors prior to the peopling of the Americas (Burnett and Wilczak 2012).

Minor anatomical variants have also been used to identify genetic relatedness among individuals in archaeological contexts. Among

these are dental conditions such as hyper- and hypodontia—numeric anomalies of the dentition characterized by supernumerary and congenitally absent teeth. Of course, the value of a genetic trait increases based on its heritability and frequency. Hypodontia of third molars is rare during much of hominin evolution but has increased over the past 10,000 years. Today, third molar agenesis may occur in up to 30 percent of humans due to evolution favoring a smaller jaw. This high frequency renders the trait less useful for identifying related individuals in a cemetery, except as one of a larger suite of traits. Conversely, extremely rare congenital variants can be very powerful for identifying genetic relatives. Enlargement of the parietal foramina, located at the upper rear portion of the skull, is estimated to occur in only 1 out of 25,000 individuals. Identification of 11 cases of this condition at a small, prehistoric archaeological site from California has been used to infer relatedness among the affected individuals, and two more cases at a site nearby suggests intermarriage or population movement (Hoffman 1976).

Coprolites

TIM RILEY

Utah State University Eastern Prehistoric Museum,
USA

Coprolite, a paleontological term of ancient Greek origin for ancient fossilized feces, was first applied to human fecal material in 1890. While these specimens, also called paloe-feces, were noted in sites from many regions by early archaeologists, there was little research on coprolites until the 1960s, when Eric O. Callen rehydrated them in a 0.5 percent trisodium phosphate solution. This technique allowed for the systematic study of the constituents of the coprolite. Even after this development, many archaeologists still did not recognize the research potential of these screen-clogging specimens, generally discarding them and even using them as Frisbees for lunchtime entertainment (Bryant and Dean 2006). As archaeologists become more interested in the ecological underpinnings of past societies, coprolites became an important dataset for understanding past diets and environments.

Coprolite formation

Coprolites are biochemically complex specimens that contain residues derived from multiple sources. Fry (1985) lists six major components: (1) undigested dietary compounds; (2) intestinal secretions of the individual, including hormones; (3) minerals and other substances excreted into the digestive tract; (4) hindgut bacteria and their metabolic derivatives; (5) cellular components, including parasites and pathological evidence; (6) enteroliths, gallstones, pancreatic calculi, and fecal spherulites. While this complexity offers a high variety of potential lines of data, the majority of coprolite studies have focused on the identification of food residues and parasites.

Coprolites represent a temporally limited window into the dietary decisions of an individual.

This record of food combinations is unparalleled as a detailed record of meals. This is furthered by the biological complexity of the specimens themselves, which allow for direct dating and for many lines of evidence on diet. However, coprolites are preserved only under conditions of desiccation, waterlogging, or freezing. Most coprolites are recovered from protected sites, such as rock shelters and architectural structures.

Macroscopic analysis

The most abundant components of many coprolite specimens are macroscopic plant and animal remains such as seeds, fiber (see FIBERS), bone (see BONES AND IVORY), hair, chitin, and scales. These components can inform us on diet but may not accurately reflect the relative importance of different food items. This is particularly true of easily digestible plant and animal components such as the soft tissue of fruits, geophytes such as tubers, skeletal muscle and other tissue from animals, or plant foods that are heavily processed before consumption, such as milled seed resources.

Microscopic analysis

Since the first studies by Paul Martin in the 1960s, pollen analysis (see PALYNOLOGY) has become a routine part of both human and animal coprolite studies. Pollen analysis is perhaps most useful in identifying the possible medicinal ingestion of plants (Chaves, De Miranda, and Reinhard 2003), though it has also been used to infer seasonality and diet.

Ova and larvae of both ectoparasites and endoparasites are the second most common microscopic component identified in coprolite studies (see PARASITE OVA AND CYSTS; Araújo, Reinhard, and Ferreira 2015). It should be noted that interpretations of these remains must be made with caution, as many parasite ova are difficult to classify or are not exclusive

DOI: 10.1002/9781119188230.saseas0131

to humans. Evidence of parasitic infestation can provide an excellent means by which to evaluate changes in community health that occurred with the development of agriculture or were due to increasing population density (see PARASITOLOGY).

Other microfossils have also been recovered from coprolite specimens: phytoliths (see PHYTOLITH ANALYSIS), starch (see STARCH GRANULE ANALYSIS), bacteria, fungal spores, and diatoms (see DIATOMS). Phytoliths (mineral structures formed in plant tissue) are the most frequently studied of these microfossils and are a better proxy for food consumption than pollen, as they may come directly from the plant tissues that were desirable foods.

There have been few attempts to look for starch in coprolites. Starch granules are direct evidence of past diet, since the starch itself is the nutrient being consumed. Starch is a highly digestible carbohydrate in the human gastrointestinal system, but research has shown that there is a great deal of variability in the digestibility of starch—which is influenced by the molecular structure of the starch itself, the complex interaction of starch with other cellular components of the food resource and of the rest of the meal, and the processing techniques involved in meal preparation.

Biochemical analysis of coprolites

The dietary data derived from the macroscopic and microscopic residues of coprolites is unparalleled in the archaeological record. Concordant lines of evidence inform on the dietary decisions underlying the meals represented in the specimen. This extremely detailed access into the decisions of an individual actor in the past is furthered by a range of molecular techniques that have been applied to coprolites.

Coprolites contain a range of organic and inorganic substances, as well as compounds at varying stages of digestive breakdown. Infrared absorption spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) has been employed to study the chemical composition of mineralized human feces. Other possible techniques for characterizing chemical compounds

include gas chromatography–mass spectrometry (GC/MS) (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)), which can also be used to monitor the light stable isotope ratios of individual compounds.

Immunosorbent assay

This technique is frequently applied to modern fecal specimens and can be used to detect a number of antigen proteins, depending on the research goal. It has been used primarily to detect evidence of parasitic infection. This technique has also been used to confirm the consumption of human flesh associated with evidence of human butchery at Cowboy Wash, Colorado (Billman, Lambert, and Leonard 2000).

aDna

Human mtDNA from coprolites can provide direct evidence of past movement of human populations and other questions of paleodemography through the evaluation of the common haplotype groups among populations. Studies at Paisley Cave have used mtDNA from coprolites to document a pre-Clovis occupation (Gilbert et al. 2008).

Much of the work on animal and plant DNA in coprolites has focused on nuclear and chloroplast DNA, since nonhuman mtDNA has a limited capacity to inform on dietary choices (see CHROMOSOMAL DNA). There are some exceptions, such as the identification of turkey domestication in the American Southwest through mtDNA markers (Speller et al. 2010). While many nuclear DNA fragments cannot be identified below the family level, corollary evidence from macroremains and microremains can improve the resolution of the resulting interpretations. Despite recent interest in gut microbiomes and the preponderance of these organisms in coprolite specimens, no attempt has been made to examine the DNA of these communities.

Steroids

Before the advent of aDNA research, steroid analysis was the most commonly employed chemical technique in coprolite studies. The analysis of

these compounds can be used to address a number of research questions. Since humans produce species-specific sterols (a subgroup of steroids found in plants, animals, and fungi) in their feces, the analysis of these compounds can inform on the presence of human fecal material in water or soil or can verify a coprolite as human in origin. Because our sex hormones (estrogens and androgens) are steroids, determining the sex has been the primary focus of fecal steroid studies in human coprolite research (Sobolik et al. 1996). There may also be some potential for distinguishing between the follicular phase and the luteal phase in coprolites deposited by women.

Stable isotopes

While stable isotope studies are routinely conducted on preserved skeletal material from archaeological sites in order to study ancient diets, there are few published studies of stable isotope data derived from human coprolites. Staple carbon isotopes inform on the use of plant resources with differing photosynthetic pathways ($\delta^{13}\text{C}$; see DIET AND CARBON ISOTOPES), while nitrogen isotopes shed light on the role and source of animal protein ($\delta^{15}\text{N}$; see DIET AND NITROGEN ISOTOPES). The relationship between dietary $\delta^{13}\text{C}$ values and the resulting $\delta^{13}\text{C}$ values of feces is complex, since fecal material represents a combination of indigestible dietary residue, the bacterial flora of the gastrointestinal tract, and cells of multiple tissue types from the individual. However, one major advantage of fecal $\delta^{13}\text{C}$ values is that they can be used to ask questions about changes in diet over much shorter time periods than the record found in bone and teeth, which represents a dietary average over a longer time span.

AMS c-14 radiocarbon

Coprolite specimens can be directly dated using accelerator mass spectrometry (AMS) radiocarbon methods. This is particularly important at sites that have been impacted by artifact collectors, looting, and animal grazing. Out-of-context specimens can be temporally associated using AMS radiocarbon dating. While coprolites do provide enough carbon to

be dated directly through traditional radiocarbon methods, there is potential for external contamination and admixture of components within the specimen. AMS dating allows for the direct subsampling of either the visible components or the general residue in the specimen without destroying a large portion of that specimen.

Coprolites are among the most biologically complex evidence of past human activity in the archaeological record. One specimen can yield multiple lines of congruent evidence on an individual's dietary choices, as well as information on seasonality of site occupation, overall health, parasite load, potential sex through sterol analysis, and even individual identity through mtDNA. This wealth of information focused on the actions of one individual over a day or two requires different frames of analysis from the archaeological palimpsest that results from the actions of multiple individuals over years and decades.

Cranial Shaping

VERA TIESLER

Universidad Autónoma de Yucatán, Mexico

The reshaping of the infant's skull counts as one of the most widespread and at the same time diversified body modification traditions in the human past. Cranial modification has been practiced in numerous areas and epochs on all continents, and has been especially well-documented in the Americas and Central Africa. Namely the Mangbetu from the Republic of Congo have practiced head elongation until recently by using constricting cords, a technique which is similar to the head modifications among indigenous peoples from the Pacific Islands. On the Eurasian continent, head modifications were practiced by multiple means and were still common in subscribed areas, such as southwest France, until the beginning of last century.

Cranial modification took place in the first few years of an infant's life while the skull is still malleable; at the age of two to three years the skull hardens and the shaping became permanent. The artificial modification of the infant head was therefore performed on newborns, babies, and toddlers. It was practiced mostly by female kin who used for this purpose daily head massages by hand, compression cradleboards, head splints, soft constricting wraps and bandages, constricting hats, or a combination of these compression devices. Most plastic modifications of the skull targeted the neurocranium exclusively, although permanent facial flattening is reported in the literature as a rare form of permanent head embellishment (Dingwall 1931, 197). Cranial vault modification appears to be a very ancient practice that goes back to hominid forms predating *Homo sapiens* (Tiesler 2014).

Cross-culturally, head shaping related to a myriad of motives related to child rearing, identity, ethnicity, status, and gender, or more vaguely, tradition and beauty. In particular, the notion of embellishment by actively shifting the head's

morphology linked its enactment and visible outcome to culturally aligned ideas of the body, physical embodiment, and constructed beauty (Bonogofsky 2011; Lock and Farquhar 2007). The public display of heads with their altered morphologies have lent themselves to studies of body discourse, performance, and body display, in which the head is regarded as a physical recipient of socially mediated action, a social canvas, that represents society as it assimilates self-assigned group identity. These concepts and other humanistic research on the relationship between the head and society, touch upon notions of physicality and corporeity, corporeality, material interaction, self-reflection and representation, and cosmological models.

Apart from such social "construction," recent inquiries of cranial shaping among archaeologically retrieved cranial series tend to be craniometric in scope and have established themselves as a formal line of research in anthropological and health-related sciences alike. Physiologically speaking, extrinsic modifications of cranial morphology are brought about in infants and small children. They are accomplished by means of massages, constriction and/or compression over prolonged periods of time. The external pressure does not cause any passive tissue retreat, but rather results in compensatory neurocranial expansion that induces the brain and the cranial vault to expand towards unrestricted areas. Natural limitations to externally-induced morphological change are induced by the maturation and/or hardening of the cranial and related connective tissues, which increasingly limit plastic change after the first couple of months of life. Apart from maturation, health risks in treated minors depend on the degree and technique of the applied extrinsic forces and the location of compression vectors on the cranium. Secondary effects may include focal infections, necrosis, and bleeding, and—albeit rarely mentioned—intracranial hypertension.

The permanent nature of most cranial modification allows scholars to study the skeletal and broader contextual record for understanding the processes involved and their possible

Table 1 Classification of artificial cranial modifications (Tiesler 2014, 72). Adapted from Dembo and Imbelloni (1938, 275).

Type	Generic compression device	Degrees [0–4]	Distribution of compression (in degrees ≤ 3)	Circular wraps [0–3]	Sagittal constriction [0–3]
Tabular oblique modification	- Fronto-occipital compression effected by a head splint	- Extreme [>3] - Intermediate [≤ 3]	- Intermediate - Curved occipital - Curved frontal - Parallelepiped - Mimetic	- Absence - Presence of horizontal constriction (pseudo-circular)	- Absence - Presence of band [$>0-2$] - Bipolar separation [>2]
Tabular erect modification	- Posterior compression in supine position in a cradleboard	- Extreme [>3] - Intermediate [≤ 3]	- Intermediate - Occipital-plane - Frontal-plane Parallelepiped Mimetic Conical	- Absence - Presence of horizontal constriction (pseudo-circular)	- Absence - Presence of band [$>0-2$] - Bipolar separation [>2]
Annular modification	- Symmetric annular constriction through elastic bands, wraps, or hats	No information	No compression plane or flattening	No information	No information

The variables that are relevant for determining the compression types and techniques (first two columns) follow as four separate columns: They relate to the severity of cranial change, the distribution of compression planes, the presence of circular constriction, and the presence of sagittal constriction.

meanings. The analytical parameters for the study of head shaping practices are generally anchored in description, craniometrics, and adapted taxonomic criteria. These have been examined within regional cultural frames. A host of taxonomic criteria have evolved over the past 200 years to classify artificial head shapes in different areas of the world, namely in the Americas (Tiesler 2014; Table 1). Here, some of the early classifications attempted to correlate specific head shapes to ethnicity or social class or to their intentional or unintentional aesthetic nature (Dembo and Imbelloni 1938; Weiss 1961). The latter admits the possibility of head flattening being the unintended side product of cradleboarding and tumpline use, for example.

Further approaches have sought to infer the compression techniques from the specific changes they have left in the cranial morphology. Such an attempt was made by the Imbelloni system, which has been adopted widely by Latin American scholarship (Dembo and Imbelloni 1938; Table 1). This taxonomy distinguishes flexible bandaging and hat constrictions from hard compression kits. While flexible devices constrict head growth symmetrically and usually result in roughly symmetric and tubular cranial vaults, hard compression devices flatten the compressed surfaces and originate the bulging of uncompressed areas of the cranial vault.

Among the rigid compression kits, cradleboards are commonly identified with broad and short head silhouettes (tabular erect head shapes) and head splinting with long and inclined heads (tabular oblique cranial vaults) (Table 1). Despite this association between specific devices and corresponding head morphologies, an ongoing discussion targets the exact implementation of compression kits and their potential combination with strings and pads. Emphasis has been placed on the importance of overall skull form and the location of constriction grooves or compression planes.

In recent decades, 3-D landmark studies have replaced descriptions, plain measurements, and two-dimensional representations. These detailed three-dimensional records of ancient

skulls have allowed scholars to deepen their understanding of the dynamics involved in extrinsic cranial change. Such methods have also replaced uni-dimensional classifications with multivariate statistics and geometric modeling. These datasets and broader bioarcheological and contextual criteria provide useful points of departure for inferring the social dimensions and temporal trends of past head-molding practices.

Craniometry

NOREEN VON CRAMON-TAUBADEL

University at Buffalo, State University of New York,
USA

Craniometry, or the quantification and comparison of human cranial form (shape and size), has been a central methodology of anthropology for several centuries. However, the guiding motivations for and underlying theoretical assumptions regarding craniometric analyses have changed substantially over time. Historically, craniometric data were largely used as a means of generating and justifying essentialist racial classification schemes (Gould 1981). Particular emphasis was placed on studying the cranium (as opposed to other skeletal regions, see OSTEOLOGY), given its association with brain growth and the predominant assumption that brain size was directly related to cognition and intelligence. It is worth noting the distinction between craniometry and the popular nineteenth-century pseudoscience of “phrenology,” which advocated that external features of the skull reflected a person’s innate talents, abilities, and personality. Largely catalyzed by the work (*De Generis Humani Varietate Nativa*) of Johann Blumenbach (1752–1840), first published in 1775, large collections of crania were amassed across Europe and the United States with the purpose of creating objective and repeatable means of quantifying cranial variation. Hence, particularly during the nineteenth century, much effort was expended on identifying particular metrics that could be rigorously and repeatedly captured from human skulls. A classic example of such a metric is the cranial index defined by Swedish anatomist Anders Retzius (1796–1860). The cranial index is quantified as maximum cranial width divided by maximum cranial length, expressed as a percentage. This ratio is still widely used in bioanthropology and bioarchaeology (see BIOARCHAEOLOGY) today as a means of assessing whether cranial samples are relatively doliocephalic (i.e., long skull compared to width) or brachycephalic (i.e., short compared to width).

Under the direction of Paul Broca (1824–1880), the French school of craniometry emphasized the need for consistent means of quantifying cranial form, describing in detail “points de repère” (points of correspondence) that could be identified on the outer surface of the skull. Broca advocated the use of Greek terms for naming these points (landmarks) (Figure 1) and his naming scheme was expanded by subsequent workers, most notably Aurel von Török (1842–1912), Paul Topinard (1830–1911), and Felix von Luschan (1854–1924). In 1937, the American biological anthropologist, William W. Howells (1908–2005), reviewed definitions of craniometric landmarks as they stood at that time, and identified several different “schools” of craniometry. The German anatomist, Rudolf Martin (1864–1925), had expanded and amended von Török’s list, while in the USA, Aleš Hrdlička (1869–1943) and Harris Hawthorne Wilder (1864–1928) were the major authorities on craniometry. In Britain, the science of craniometry was largely directed by the Galton laboratory at University College London, which adhered strongly to the measuring scheme set out by the Frankfort Agreement. The Frankfort Agreement was an attempt to standardize craniometric schemes, reached during the 13th general congress of the German Anthropology Society held in Frankfurt-am-Main in August 1882. The final version of the agreement was published in the *Archiv für Anthropologie* in 1885. One major outcome of this agreement was a standard way to orientate the cranium when taking measurements using a plane drawn from the base of the two eye orbits and the top of the external ear opening. This plane, known as the Frankfort horizontal (Figure 1), is still in common usage today.

While the Frankfort Agreement went some way towards standardization, large-scale differences in craniometric methodology still abounded, such that another congress was organized in Monaco in 1906 in an attempt to finalize a common craniometric scheme that would receive widespread international recognition. However, this congress was only partially successful in terms of reaching a unanimous

DOI: 10.1002/9781119188230.saseas0139

Figure 1 Human cranium in lateral (a) and superior (b) view showing the position of the Frankfort horizontal (FH) and five classic craniometric landmarks, which differ in terms of how they are defined. Open circles depict landmarks defined in reference to discrete anatomical features, such as suture intersections. Glabella (diamond) is defined as the most prominent point on the anterior median plane when the skull is in FH. Euryon (star) is defined purely as being the bilateral endpoint(s) of the greatest breadth across the skull, and is, therefore, defined on the basis of measurement and not by specific anatomical features.

agreement among researchers from different countries. Nevertheless, as a result of the industry of anthropologists such as Rudolf Martin (1914) and William Howells (1973), standardized schemes were developed with attendant detailed descriptions for how data should be taken in practical terms. William Howells was particularly influential as he laid out clear instructions on how landmarks should be identified (see Figure 1 for some classic cranial landmarks) and how measurements should be taken, as well as providing clear explanations as to how his definitions differed from those of other workers.

“Traditional” craniometrics, therefore, deals with the quantification and analysis of linear measurements (i.e., distances between two cranial landmarks), angles drawn between three landmarks, and ratios of linear measurements (see also MEASUREMENT THEORY). Typically, such traditional craniometric measurements are taken with a variety of handheld calipers designed to allow access to different parts of the skull. Many anthropologists follow the system outlined by Howells (1973), which includes the major dimensions of facial and cranial width, length, and chords and angles that describe the curvature of the major bones of the cranial vault. In 1996, Howells published his full craniometric dataset of over 2,500 crania representing 28 globally distributed human populations

(see HUMAN POPULATIONS). Hence, in the past 20 years, numerous studies have been published reanalyzing these data or using them as a comparative context for understanding patterns of cranial affinity between modern or past human populations. Most craniometric analyses involve the measurement and comparison of more than two traits (bivariate analysis) and are therefore considered multivariate analyses (see MULTIVARIATE ANALYSIS). Such analyses require the comparison of variance within traits and covariance between traits (see ANALYSIS OF VARIANCE AND COVARIANCE) as a means of quantifying the average differences in cranial form within- and between-groups. The potential differences in cranial form between individuals can then be visualized by decomposing a craniometric data covariance matrix using, for example, principal component analysis (see PRINCIPAL COMPONENT ANALYSIS). Alternatively, it is possible to convert the craniometric data into a between-groups distance matrix (see BIOLOGICAL DISTANCE), sometimes referred to as a biodistance matrix. The among-group affinity pattern coded in the distance matrix can then be visualized using methods such as principal coordinate analysis, multidimensional scaling or cluster analysis (see CLUSTER ANALYSIS) to see which groups resemble each other most closely in overall cranial form.

In recent decades, bioanthropologists have been turning to newer geometric morphometric (see GEOMETRIC MORPHOMETRICS) methods as a means of quantifying and visualizing the shape of different skeletal elements (see HUMAN SKELETAL DATA QUANTIFICATION). Geometric morphometrics operates by directly analyzing the covariance within configurations of landmark coordinates captured in two (x, y) or three dimensions (x, y, z). From a statistical viewpoint, traditional caliper-based methods can provide data that are just as powerful for capturing overall cranial shape as landmark-based methods, but the advantage of geometric morphometrics is the ability to visualize the shape transformation of the whole configuration simultaneously, rather than trying to interpret shape differences one metric measurement at a time. Landmark coordinates can be captured in two dimensions from photographs, or in three dimensions directly from the skull or mandible using a handheld digitizer. In recent years, researchers are increasingly using laser (see LASER SCANNING) or structured light scanners to capture 3D models of crania, which can then be virtually measured or landmarked. These scanning methods for capturing craniometric data are particularly useful in the case of archaeological remains which may be very fragmentary, as the method is noncontact and can also be used for the virtual reconstruction of incomplete cranial specimens. While traditional linear distance measurements can be directly compared from one cranial specimen to the next, in the case of landmark configurations it is first necessary to statistically transform the raw landmark (x, y, z) coordinates such that variation in the position of one landmark relative to the other landmarks can be quantified. The most common method for doing this is called generalized Procrustes analysis (GPA) and it works by translating all landmark configurations to a common origin, scaling each configuration to a single unit size, and then rotating each configuration such that the overall deviations between homologous landmarks are minimized. The resultant landmark coordinates (Procrustes variables) are now directly comparable across specimens and can be subject to standard multivariate statistical methods as described above.

In bioarchaeology, the most common type of analyses that utilize craniometric data are biodistance studies. The basic premise underlying

such analyses is that patterns of among-group craniometric affinity patterns reflect underlying patterns of neutral genetic variation. This premise is justified because numerous studies have shown that modern human cranial shape diversity patterns reflect neutral microevolutionary forces of mutation, gene flow, and genetic drift (von Cramon-Taubadel 2014). Moreover, the majority of standard craniometric traits are at least moderately heritable (Carson 2006). Hence, when samples of crania are found to resemble each other more closely, it is reasonable to assume that this reflects a closer degree of relatedness either because they recently diverged from the same ancestral population or because they have been exchanging migrants (gene flow) to a greater extent. This association between craniometric data and underlying neutral genetic variation is useful because it allows archaeologists to utilize craniometric data in cases where genetic data are unavailable or unattainable. Therefore, craniometric data can be used to test specific hypotheses (see HYPOTHESIS TESTING) about the factors that might be responsible for particular biodistance patterns, such as the influence of external migration into a population, the impact of cultural contact and exchange between populations, as well as reconstructing the past population history of a sample of archaeological sites spread across time and space. Such hypotheses are often tested by correlating (see REGRESSION AND CORRELATION ANALYSIS) craniometric biodistance matrices against distance matrices that reflect these hypothetical phenomena such as geographic as well as temporal distance, cultural group affinity patterns, or matrices reflecting specific dispersal events.

Cross-Sectional Geometry

JOHN D. POLK

University of Illinois at Urbana–Champaign, USA

Cross-sectional properties (CSP) describe the distribution of cortical bone on any two-dimensional section through the shaft. CSP have been widely employed to make functional inferences about the predominant directions or magnitudes of loading experienced by limb bones and mandibles of humans, hominins, and other vertebrates, and to infer behavioral differences between human populations (Ruff, Holt, and Trinkaus 2006).

If a bone can reasonably be modeled as a structural beam (where length is much greater than width), CSP may reflect the bone's ability to resist mechanical loads. Cortical area (CA) reflects structural resistance to compressive or tensile loads. Second moments of area ($I = \int x^2 dA$, where x is the distance to a neutral axis of bending (NA) and dA is a unit of area) describes stiffness or resistance to bending about the NA (Figure 1a). Polar moments of area ($J = \int r^2 dA$) describe bone distribution around a longitudinal axis and reflect torsional rigidity. Section moduli ($Z = I/r$, where r is the radius in the direction of bending) reflect strength in bending or torsion (Wainright et al. 1976). CSPs are often highly correlated with bone length and body mass (Polk et al. 2000).

During animals' juvenile growth periods, bone responds to mechanical stimulation, and individuals experiencing greater loads demonstrate greater subperiosteal bone apposition than individuals experiencing less mechanical stimulation (Lieberman et al. 2003). When growth ceases, subperiosteal apposition becomes negligible, changes in CSP occur more slowly, and endosteal resorption may play a larger role in altering CSP (Ruff et al. 2006).

Functional interpretations of CSP are dependent on many assumptions and should be approached with caution. The primary assumption is that the distribution of cortical bone directly reflects the history of mechanical

loading. In this simplistic view, the processes of bone formation and resorption are assumed to provide maximum structural reinforcement with a minimum of bone material, with bone being deposited in areas that experience the highest strains. While mechanical loading clearly has an important effect on bone morphology, and strain does influence bone's response, the question of which strains (e.g., magnitude versus frequency versus rate) are most influential remains open. *In vivo* bone strain experiments have demonstrated that bones are not habitually loaded in directions that develop greatest structural reinforcement (Demes et al. 2001; Lieberman, Polk, and Demes 2004; Figure 1b), and bone is not deposited preferentially in areas that experience the highest or lowest strains. CSP are likely affected by a broad range of stimuli that bone cells experience in daily functional activities, and any simple functional interpretations of bone CSP—particularly the directionality of historically applied loads—are likely to be incorrect.

A second assumption derives from how CSP are calculated for extinct species (or any element for which *in vivo* strain data are not available). Without strain data, I and J are calculated from NA assumed to pass through the center of the bone cross-section. This assumption is false in theory and experiment (Figure 1b). Since most bones are loaded in some combination of bending and compression, the NA will be shifted toward the side of the bone that is experiencing tension. The amount of NA displacement is dependent on the ratio of compression to bending, and without strain data this amount cannot be known. Furthermore, the position of the NA is not stable during bone loading and may rotate substantially during loading cycles. Assuming that NA passes through the center of the cross-section results in errors exceeding 50 percent (Demes et al. 2001; Lieberman et al. 2004).

Some approaches to interpreting CSP are more reliable. For example, CA are not calculated using NA, and are not subject to the errors inherent in I , J , or Z . However, because bones are not loaded in pure compression or tension, the extent

Figure 1 (a) Model of a curved, cylindrical beam subjected to axial loading (F) that generates bending strains with tension (+) and compression on opposite surfaces (-), with an assumed midline neutral axis (NA) that experiences neither tension nor compression. Resistance to bending moments is proportional to I . (b) Cross-section of a sheep tibia with the experimentally determined NA at midstance (dashed line) compared to position of NA assumed to pass through the area centroid and which gives the maximum value for I . Assumed and actual NA differ dramatically and result in very different estimates of CSP.

Source: Reproduced from Lieberman, Polk, and Demes 2004, with permission of Wiley.

of functional inferences from CA is limited. Second, when CSP are compared among bony elements from groups that have similar loading patterns (e.g., among human groups), the relative differences in CSP can be informative.

While CSP have been widely interpreted to indicate biomechanical and functional differences between individuals and species, these interpretations should be treated with caution. Bone morphology is not determined solely by functional demands related to mechanical competence. Other factors such as diet, hormonal status, marrow storage, reproduction, and mineral storage all play roles in determining diaphyseal properties and shape (Turner 2001; Ruff et al. 2006).

Degenerative Joint Disease

ELIZABETH WEISS

San José State University, USA

Degenerative joint disease (DJD), also called osteoarthritis or osteoarthrosis, is a chronic, progressive deterioration of moveable joints. It is ubiquitous in both past and present populations, but past and modern populations differ greatly in which joints are affected and in DJD rates. For example, DJD of the knee, which is pervasive in present populations, was rare among ancient populations, but elbows, which are not usually afflicted with DJD in modern groups, were commonly affected in the past. Furthermore, ancient arctic populations have extremely high DJD rates, often attributed to the physically demanding lifestyle that would have been required of these peoples. However, climate has been shown to affect DJD frequency and severity (Kalichman et al. 2011).

To record DJD, osteologists look at joints for porosity (small holes), eburnation (a shiny polish caused by bone-on-bone rubbing after cartilage erosion), and osteophytes (excess bone growth), which can lead to a bony lip around the joint that may eventually lead to joint fusion. All three of these bony features can be seen in Figure 1. Medical researchers diagnose DJD through X-ray evidence of joint space narrowing and cartilage tears and hardening. Both archaeological and medical researchers identify DJD through the appearance of osteophytes. Not all osteologists agree that porosity and osteophytes are conclusive indicators of DJD; thus, some researchers suggest that only eburnation should be used as a DJD indicator. An accepted practice is to record DJD as being present on a skeletal individual if there are osteophytes and porosity present on a joint, whereas eburnation alone can be recorded as confirming an occurrence of DJD. Eburnation, the least common of the three features, is a good indicator of severe DJD.

Osteophytes have not been viewed as favorable DJD indicators because of their high correlation with age (Weiss and Jurmain 2007). Vertebral DJD, for instance, is mostly marked by osteophytes, and vertebral DJD is also strongly correlated with age. Yet, eburnation and porosity also correlate with age. Thus, age is the best predictor of who experienced DJD. The reason for the strong association between age and DJD is not well understood. The age effect may be in large part due to wear-and-tear on joints, especially if daily activities were strenuous and started early in life. Although age increases DJD in nearly all populations, researchers of past populations also report that DJD started earlier in life than in contemporary populations. This difference has led some bioarchaeologists to question whether the high heritability of DJD found in research on modern populations, mainly revealed through twin studies, may not apply to past populations. The strenuous lives of past peoples may override the weight of genes' impact. Further, medical researchers suggest that early-onset DJD is likely related to activities; for instance, former youth athletes have higher rates of DJD compared to nonathletic individuals. Nevertheless, age controls are essential when examining DJD; unfortunately, osteological adult age estimates are imprecise (see ESTIMATING ADULT AGE: AURICULAR SURFACE MORPHOLOGY; ESTIMATING ADULT AGE: PUBIC MORPHOLOGY; and ESTIMATING ADULT AGE: TRANSITION ANALYSIS).

While DJD etiology is acknowledged to be multifactorial, most bioarchaeologists who study DJD, like those studying musculoskeletal stress markers (see MUSCULOSKELETAL STRESS MARKERS) and cross-sectional geometry (see CROSS-SECTIONAL GEOMETRY), do so to reconstruct activity patterns. Questions regarding sexual division of labor, workload differences dependent on subsistence patterns, and class differences in occupations have all been addressed using DJD. DJD became used as an activity reconstruction marker after pioneering work in the 1960s and 1970s by J. Lawrence Angel, Calvin Wells, and David J. Ortner, all of whom focused

the discussion of DJD around activities and used artifacts to help support their conclusions. Anthropologists further support their assumption that activity is the main cause of DJD by citing studies on living populations that report significant correlations between DJD and specific activities or occupations (Weiss and Jurmain 2007).

Sometimes differentiating the activity causes of DJD from other factors can be difficult. For instance, individuals who engaged in physically demanding activities may be prone to trauma (see TRAUMA), which can result in localized DJD later in life. Similarly, high rates of DJD among farmers may relate to zoonotic (animal-borne) infectious diseases (see INFECTIOUS DISEASE). Certain infectious agents, such as those that cause Lyme disease, are known to cause DJD. In modern populations, obesity has been associated with an increase in DJD, which was thought to be related to the mechanical stresses affecting weight-bearing joints, but obese individuals also have higher DJD rates in non-weight-bearing joints. The body's inflammatory response has been suggested as the culprit behind the DJD and obesity link. Furthermore, DJD often afflicts

multiple joints in a single individual, which implies that DJD is systemic. The systemic cause may relate to bone turnover, which could explain why some researchers find that individuals with DJD are less likely to have osteoporosis (Weiss 2015).

The high frequency of DJD in archaeological collections makes it impossible to ignore. Future researchers may wish to examine DJD from multiple perspectives. Looking into past and present trends may help anthropologists determine the types of DJD that can be used for activity reconstructions. Conversely, using DJD for age estimation may be an attainable goal when looking at universal trends.

Dental Decoration

VERA TIESLER

Universidad Autónoma de Yucatán, Mexico

Decoration of the teeth has constituted a widespread form of body modification, which has been documented globally. The methods of culturally enhancing teeth range from temporary or semipermanent dental works (painting, discoloration, cauterization, applications, and prosthesis) to permanent removal or modification of single teeth and sets of teeth (Alt and Pichler 1998; Dembo and Imbelloni 1938; Milner and Larsen 1991). This entry focuses on the latter. Permanent dental reduction counts as an artificial corporeal modification, defined anthropologically as the procedures on the human body that are carried out with the purpose of modifying its external aspect (Alt and Pichler 1998). Although this definition does not include and often explicitly excludes external adornments, these body ornaments cannot be conceived as a separate entity. Namely, tooth contouring would often be complemented or highlighted by external facial adornments. In this same logic, dental drillings of anterior teeth cannot be understood properly if not conceived in the context of the amalgams or inlaid stones that these dental voids would hold.

When intended for adornment, permanent dental alterations appear typically on the visible segment of the dental arch. Across the globe, these works have been accomplished with different techniques, such as ablation (tooth extraction), flat abrasion by filing, cutting, chipping, engraving, drilling, and incrustation. The host of dental decorations, and the added and inlaid materials that have been documented in traditional societies demonstrate the diversity of regional and local custom. Practiced mostly on adolescents and young adults, the initial interventions were often followed by subsequent maintenance, especially once tooth wear and decay set in or if oral complications occurred.

Distribution

Permanent dental decorations constitute an important means of cultural embodiment (Milner and Larsen 1991). This includes northern Africa and prehistoric Europe, where intentional modification appears in several Neolithic teeth from Matadepera, Barcelona. The remains of several Danish Vikings display deep horizontal grooves on their front teeth. Tooth evulsion (extraction) appears to be very ancient, as noted among North African skulls dated to the Mesolithic, although the dating of these remains is uncertain (Tiesler 2000).

Permanent dental modifications were customary also in areas of Australia, Polynesia, and Asia, namely in Bali, Pakistan, the Malayan Archipelago (Java, Sumatra, Celebes, Borneo, Philippines), Vietnam, China, Japan, and Taiwan. On the African continent, dental modification has been documented in ancient Egypt, Nubia, and large segments of sub-Saharan West Africa and the Congo. In Africa, dental extraction, filing, fracturing, and chiseling were (and in some areas still are) the preferred techniques to obtain the desired tooth contours. Beginning in the Middle Ages, some dental practices spread out of Africa, especially during the Muslim invasion in Spain and the European occupation of the Americas. Such traditional dentistry is seen in African-born individuals who had been introduced to the Americas as slaves. These African-derived dental works provide important clues to trace the geographic provenience and group affiliation of some historic African-American populations (Handler, Corruccini, and Mutaw 1982).

In the post-conquest Americas, African tooth modifications sometimes blended with dentistry practiced among Mesoamerican societies at the onset of colonization and which included grooving teeth or filing teeth to a point (Romero 1958; Tiesler 2000). In the millennium prior to European conquest, the dental modifications found in the Americas were more varied. During the Classic period (250–900 CE), the dental

modification repertoire of Veracruz, Oaxaca, and the Maya area of Central America included sophisticated forms of single and multiple drillings, which held cemented semiprecious stones or colorful fillings (Romero 1958; Tiesler 2000). To our present knowledge, all Mesoamerican tooth decorations appear to have been accomplished by way of filing, scraping, and drilling. Inlays held differently colored pastes or cemented stones, including stone incrustations crafted into the form of flat or protruding plugs. Further south, in Ecuador (Esmeraldas), metal squares were fitted into horizontal notches, while the teeth of ancient Peruvians and Argentinians were contoured into different shapes. North of Mesoamerica, filings were customary among North American tribal nations in what is now Arizona, Illinois, Tennessee, Georgia, and Texas (Milner and Larsen 1991).

Forms and techniques

The permanent dentition was clearly the target of traditional dental modification. Adult dentine is 3–4 on the Mohs hardness scale (similar in hardness to platinum), while enamel is even harder (5 on the Mohs hardness scale, harder than steel and as hard as obsidian). Modifying teeth is similar in many ways to stone and shell crafting. Either hard abrasive stones or blends of volcanic ash and/or abrasive sand are needed to manually wear down dental tissues.

Cross-culturally, filing was and still is the most common traditional method used to modify tooth shape. Filing involves the gradual and selective attrition of the tooth surface until the desired form is achieved. The exposed and abraded dental surfaces would sometimes receive a finishing polish. Similar to flat abrasion is the procedure of cutting or carving teeth with abrasive cords, sharpened stones, or metal knives. The latter commonly leave notches or narrow grooves on the anterior tooth surfaces or their incisal edges.

An alternative form to gradual dental decoration is complete or selective tooth fracture. Indirect percussion (chiseling) has been documented in traditional African and African-American dental works (Milner and Larsen 1991). These

precision blows were typically directed to the occlusal edges of anterior teeth. Tooth fractures were achieved by a single blow with a hammer or by gradually flaking off dental edges with small chisels.

Much more complex and prolonged than polishing, filing, engraving, or percussion were the procedures involved in preparing dental inlays. In the case of the ancient Maya or the Zapotecs, these were carried out in sequential operations before the final product was obtained (Fastlicht and Romero 1976; Tiesler, Cucina, and Ramírez-Salomón 2017). After an initial notch centered on the labial tooth surface was created, precision drilling was performed to penetrate the enamel and part of the dentine. Drilling was likely performed with chert tools, assisted by abrasive sands. The unfinished dental pit was worked further until its bottom was flat and its walls roughly perpendicular to the outer dental surface. Dental drilling usually penetrated into the dentine layer and could in rare occasions also collapse into the pulp chamber, causing health consequences to the person who underwent the procedure. When created successfully, the dental cavity was filled with colorful pastes or a previously fitted, barrel-shaped piece of jadeite, pyrite, or turquoise. The semiprecious stones were sealed into the opening with a calcite-based cementing material. Most of the dark inlays, identified either as pyrite or hematite, show a mirror-like surface in the Maya area, whereas green jadeite inlays would typically protrude over the dental surface as domes. The drilled dentitions of some pre-Hispanic Maya, such as a number of Classic-period settlers of the Copan Valley in Honduras, received round mushroom-like plugs. Their stem firmly anchored in the tooth cavity, these stones were topped with a much larger flat disc that would appear as large, colorful circles in the open mouth of their carriers (Fastlicht and Romero 1976; Romero 1958; Tiesler 2000). Many operations concluded with polishes achieved by rubbing the anterior teeth systematically with pastes of volcanic particles or any other polishing matter sufficiently fine and hard to act on enamel and dentine. Apart from the exposed dental plane, dental burnishes could sometimes extend over the entire anterior surfaces, producing a shiny smile.

Health risks and motivations

Despite the high success rates that the literature reports of traditional dental procedures, they could sometimes lead to discomfort and health consequences during and after the initial operation. The extent of potential hazards has not been the subject of systematic scrutiny, although modern dentistry does not leave much room for doubt that the stresses exerted by changing the physiological form of the teeth must have decreased masticatory functionality and increased the rates of infectious decay and premature tooth loss.

Apart from purely orthodontic considerations, dental decorations have received attention in both popular and scientific writings. However, surprisingly little is known about the plethora of culturally sanctioned purposes and subtle meanings of dental modifications beyond simplistic ad hoc assertions, such as its practice during rites of passage and for purposes of personal embellishment. The lived experiences attached to dental modifications are much more complex and multilayered, of course, as they unfold a host of culturally aligned motivations that range from symbolic identification, markings of identity, personal choice, and therapeutic measures. These in turn warrant a closer scrutiny of the underlying ideological aspects, including body and gender concepts, ritual choreographies and social structure, even culturally sanctioned esthetics and concepts of beauty.

In their customary dimension, dental alterations are commonly associated with puberty rites or rites of passage, which are gender distinctive in some societies. In some societies, dental modification may relate to prevention and punishment. In either connotation, the endurance of pain could be an integral or even desired part of the dental modification procedure. Also, more mundane motives are cited, such as nourishment, reproductive fitness, or curing. Modified dentitions constitute a powerful space of physical embodiment that epitomizes social identities. The public display of these dental makeovers holds meanings for each individual with modified teeth.

Methods of studying dental decoration from the archaeological record

Descriptive case studies of ancient dental work still prevail over systematic coverage. Standard taxonomies commonly distinguish techniques or instruments; others classify the artificial shapes of teeth and dentitions. Most of these taxonomies have been elaborated for specific cultural spheres. Among the latter, the elaborate nomenclatures by Rubín de la Borbolla and especially by Javier Romero (1958; Fastlicht and Romero 1976) have been continually used by scholarship. Both are geared towards Mesoamerican and in general the American continent. Romero's table distinguishes seven groups of dental reductions according to contour and surface treatment. Its use over the last decades has promoted a more systematic coverage of culturally defined patterns of tooth work in the Americas and beyond.

The culturally induced nature of this body practice allows scholars to contextualize the technical and physiopathological characteristics of dental works according to mortuary associations, cultural landscapes, and temporal trends of dental modifications in skeletal populations. Conventional odontological studies of dental decoration have been increasingly complemented with 3D surface modeling, optical microscopy, dental radiography, X-ray tomography, and scanning electron microscopic analyses that provide ever more detailed information about the methods and sequence by which teeth were modified.

Dental Development

MARIN A. PILLOUD and KELLY HEIM

University of Nevada, Reno, USA

The process of dental development (odontogenesis) begins in utero and continues until the closure of the apex (tip of the root) of the permanent third molar at roughly the end of adolescence or the beginning of early adulthood. Teeth develop and erupt in a predictable sequence, which allows for estimations of subadult age (see ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION). As teeth are not subject to plastic changes throughout one's life (unlike bone), they can serve as a record of embryological development through late adolescence. Therefore, studies of the dentition can address various hypotheses in archaeological contexts regarding growth and development; life history; and childhood diet, mobility, stress, and pathological conditions. An understanding of how teeth develop is salient to not only pursuing these research questions, but also other bioarchaeological studies of the teeth (e.g., those involving dental metrics and morphology).

Teeth are composed of a crown and a root. The outer crown is made of enamel—a hard acellular tissue that is almost entirely inorganic. After formation, maturation, and eruption, the enamel-forming cells (ameloblasts) are lost and enamel cannot be reformed. The inner portion of the tooth is composed of dentine that extends through the crown and root. Dentine forms the bulk of the tooth; it is roughly 70 percent inorganic and is not as hard as enamel. The root is then covered with cementum, a bone-like layer of connective tissue that serves to anchor the periodontal ligaments that hold the tooth in place. Unlike enamel, dentine and cementum can be created after initial dental development (via odontoblasts and cementoblasts, respectively). Nerves and vessels enter the tooth via the apex of the root to populate the pulp cavity (Figure 1).

During dental development, dentine is laid down first, enamel second (over the forming

dentine), and the root and cementum are formed last. Formation of these tissues begins at the tip of dentine (i.e., dentine horn) in the area that will become the future cusp. Development then progresses down the tooth towards the roots. Enamel formation ceases once the crown is complete, dentine formation continues to the root apex, and cementum formation follows that of the root. This process of odontogenesis is recorded in the histological structures of the teeth, which can be seen in cross-section. As ameloblasts move from the dentin–enamel junction to the outer crown, they create enamel rods (or prisms). Within these rods, there is evidence of short- and long-period increments of development. The short-period increments manifest as cross-striations and represent approximately 24 hours of growth. Long-period increments occur around every eight or nine days when development slows. This slowing manifests as dark bands, called the striae of Retzius. These striae outcrop on the surface of the enamel as transverse ridges called perikymata (see Figure 1). Each perikyma is representative of approximately eight to nine days of growth, which can be verified through an analysis of the cross-striations (Nanci 2003).

Early on, dental development is largely independent of sex; however, at later stages (into adolescence), females begin to develop teeth ahead of males. Around the seventh week of gestation, both the maxillary and mandibular deciduous incisors and canines begin to develop. The deciduous enamel crowns are almost completely developed by the first year. During the sixth month in utero, the maxillary and mandibular permanent incisors and canines begin to develop. The enamel crowns of permanent teeth are generally complete by eight years of age, with the third molar crown reaching completion between 12 and 16 years of age. Root formation continues beyond enamel development, with all roots of deciduous teeth being completed between approximately 18 months and three years, and roots of permanent teeth completing between nine and 16 years, with third molar root completion between 18 and 25 years of age (Schuurs 2012). It is important

Figure 1 Cross-section of a typical lower molar illustrating the macro- and microstructures of the teeth.

to point out that crown and root development is related to, but separate from, dental eruption (see ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION). Eruption is the process of tooth migration through the bony structure of the jaws to a final position of occlusion, whereas dental development is the process of tooth formation.

The development and differentiation of teeth into different types, or tooth classes (e.g., incisors, canines, premolars, and molars), is a complex process. Historically, there have been two main theories surrounding this procedure (i.e., dental patterning): the field and clone theories. The field theory posits that each tooth type develops correctly due to a “field” effect surrounding the teeth produced by various signals. A. A. Dahlberg (1945) further added that the more mesial tooth (i.e., towards the midline) in each class would be under the strongest influence of the “field” and would therefore develop first and be the least variable. These more stable mesial teeth are called the “key” or “polar” teeth (with the exception of the lower lateral incisor, which is the key tooth

as it shows less variation than the lower central incisor). Alternatively, the clone theory suggests that each tooth class is formed by cloning cells from the location of the first tooth. As the cloning process moves distally, the teeth become more variable.

More recent genetic research has shown that homeobox genes in neural crest cells (special cells that arise from embryonic ectoderm) are largely responsible for directing odontogenesis during embryological development. Further, the signaling molecule ectodysplasin has been found to play a role in determining dental field size, which can be involved in the presence of supernumerary or missing teeth. This understanding of genetic development has been combined with the field and clone theories to advance a model termed the “cooperative genetic interaction.” In this synthesis, the roles of homeobox genes, signaling molecules, and neural crest-derived cells are acknowledged as contributing to development and tooth differentiation (Mitsiadis and Smith 2006). These three factors can be used to explain cloning (via cell division) and morphogenetic

fields or signals (homeobox genes and signaling molecules).

Dental development can also play a role in crown trait expression (see DISCRETE TRAITS). Formation of the hard tissues of the crown (i.e., enamel and dentine) is triggered through chemical signaling centers called enamel knots (Nanci 2003). Single-cusped teeth (i.e., incisors and canines) possess only a primary enamel knot, whereas multicusped teeth (i.e., premolars and molars) form secondary enamel knots during odontogenesis. These secondary enamel knots release proteins that act as both activators and inhibitors. Activation proteins trigger ameloblasts and odontoblasts to begin hard tissue production, while inhibition proteins prevent subsequent secondary enamel knots from forming nearby. A larger inhibition field produced by a secondary enamel knot will increase the amount of space between cusps. Additionally, if secondary enamel knot formation is delayed, the subsequent cusp will be shorter in relation to the previous cusp. This patterning cascade model of cusp formation suggests that the genetic code for the formation of a secondary enamel knot is repeated during odontogenesis. As the code repeats, variation accumulates, resulting in later developing cusps becoming more variable (Jernvall and Jung 2000).

Several research questions can be pursued based on this knowledge of dental development. For example, among primates, life-history traits track with these developmental processes, including weaning, the end of adolescence, and overall lifespan. Additionally, the development and eruption of teeth has been linked to brain size in primates. Generally, as brain size increases, more energy is funneled to growing a larger brain, which results in a slowing of dental development and eruption. Therefore, research on crown formation rates among various hominin species can provide information about our evolutionary past and the emergence of these life-history traits. Studies on the microstructure of teeth of early hominins, such as australopithecines and *Homo erectus*, indicate these species had shorter formation times than are seen among anatomically modern humans (Dean et al. 2001). However, Neanderthal crown formation times seem to be in line with those of modern humans (Macchiarelli et al. 2006), thereby indicating that slowed dental

growth was a relatively recent development in human evolution.

In archaeological research, stable isotope analyses are also regularly performed on teeth. As teeth are formed early in life, their isotopic signatures can serve to answer questions surrounding childhood diet (carbon and nitrogen; see DIET AND CARBON ISOTOPES and DIET AND NITROGEN ISOTOPES) and mobility (strontium and oxygen; see MOBILITY AND OXYGEN ISOTOPES and MOBILITY AND STRONTIUM ISOTOPES). These studies can be undertaken on large sections of the dental tissues to broadly represent childhood, which can also be compared to bone (representing the last several years of life) to study diet or mobility changes throughout one's lifetime. It is also possible to analyze several smaller sections within a single tooth (or individual) to represent specific periods of development. Careful analysis of the isotopic signature of these different layers can show intra-individual changes in diet or movement across the landscape at a more fine-grained scale.

Within bioarchaeological research, the sensitivity of dental enamel development to stress episodes can serve as an indicator of physiological growth disruption. Within the internal structure of enamel, as viewed in cross-section, pronounced striae could indicate a disruption of enamel secretion. The neonatal line is a prominent line found in teeth developing at the time of birth and is thought to be related to the birth event. Additionally, other so-called pathological striae, or Wilson bands, could be indicators of growth disruption, although a clear link has not yet been found (Hillson 1996). Similar disruptions are visible in the dentine as contour lines of Owen. These accentuated lines, such as an exceptionally large striation in relation to birth and the neonatal line of the enamel, are related to periods of stress (Nanci 2003). On the surface of the crown, enamel deposition disruption can be seen as enamel hypoplasias. These enamel defects are related to nonspecific stress during development and appear as furrows (linear), pits, or plane-defects (large exposures or irregular facets). Based on what is understood about crown formation, duration of stress episodes can be estimated (based on perikymata counts), as well as age of occurrence (calculated from known formation rates). Finally, there is

evidence to suggest that tooth dimensions of the deciduous and permanent teeth can be reduced during development in cases of maternal or fetal stress. Additionally, dental asymmetry between antimeres (paired teeth on right and left sides) has been linked to physiological stress in human and animal studies (Hillson 1996).

In addition to nonspecific indicators of dental growth disruption, there exist other abnormalities of enamel formation in relation to various factors. Excessive fluoride can cause enamel defects to include opacities and hypoplastic defects. Congenital syphilis can alter crown formation of the incisors (Hutchinson's incisors) and molars (Moon's and Mulberry molars). And, very rarely, enamel defects can be inherited, as in the case of the genetic disorder amelogenesis imperfecta (Hillson 1996).

Dental Metrics

ANDREW K. SCHERER

Brown University, USA

In biological distance studies, dental metrics are used to investigate population history and structure across global populations, among sites within an archaeological region, and even within a single community. Global studies consider differences in tooth size as well as tooth shape, which are assessed through a variety of indices derived from unidimensional measurements. The use of teeth in population studies benefits from a number of factors including the generally better preservation of teeth (relative to the rest of the skeleton), the inexpensive cost of such research, and the non-destructivity of dental measurements. Moreover, morphometric approaches remain preferable for studies of population dynamics in parts of the world where poor skeletal preservation continues to prove an obstacle for ancient DNA analyses. Tooth size and morphology are also under strong genetic control, and dental development is less affected by stress than other aspects of the skeleton. However, wear and other forms of tooth damage are obstacles to population studies based on dental measurements.

Measurements of human teeth are taken using sliding calipers with extremely fine or needle-nose tips. The most common measurements collected are the mesiodistal length of the crown, buccolingual breadth of the crown, and crown height. Most researchers follow Moorees and Reed's methodology (1964) as reprinted in the *Standards for Data Collection from Human Skeletal Remains* (Buikstra and Ubelaker 1994, 62), among other sources (Hemphill 2015). Mesiodistal length is measured either between the interproximal points of contact or as the maximum length of the tooth crown in the mesiodistal plane (the latter approach is generally preferred). Breadth is measured as the maximum width of the tooth perpendicular to the mesiodistal plane. Height is measured on the buccal surface and is taken as the distance from the occlusal edge

to the cementoenamel junction. For molars, the measurement is taken on the mesiobuccal cusp. Since tooth length and width may be affected by dental wear, some researchers prefer instead to measure tooth dimensions of the cervical region (cementoenamel junction) (Hillson, FitzGerald, and Flinn 2005), although problems have been noted with this approach (Stojanowski 2007). Cervical measurements require the use of sliding calipers specifically designed for reaching over the tooth crown unless teeth are retained in alveolar sockets. Although measurements of three-dimensional images of teeth have been employed for taxonomic analysis in paleoanthropology, this approach has thus far received little use in bioarchaeology, but may prove a fruitful avenue for future research (Hemphill 2015, 289–290).

Dental metric approaches to biological distance capitalize on a more robust body of statistical approaches relative to studies that rely on categorical data (skeletal and dental nonmetric analyses). Among the multivariate approaches to the analysis of dental metric data, the most frequently used statistic is Mahalanobis distance (D^2). This statistic is used to measure the dissimilarity of two groups (i.e., skeletal samples) based on the mean, variance, and covariance matrix of the independent variables (i.e., tooth measurements). The popularity of the D^2 statistic derives in part from the fact that it takes the intercorrelation of variables (i.e., tooth measurements) into account. D^2 analysis produces a matrix of pairwise distances among all of the skeletal samples in the study. A variety of approaches are used to better interpret the D^2 matrices, including cluster analysis and multidimensional scaling. Interpretation generally follows that skeletal samples with low-distance values represent ancient populations of common ancestry and/or ones that experienced frequent gene flow between one another relative to those with larger distance values. This approach does not, however, take into account differential population size and random sampling (i.e., genetic drift), and their potential effect on phenotypic variability among populations.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

John Relethford and John Blangero (1990) developed a model for quantitative traits to compare observed and expected heterozygosity among sampled groups as a means of reconstructing past gene flow. This model, variously known as the Relethford–Blangero approach or the *R* matrix approach, has become popular among bioarchaeologists working with metric data (*R* is the genetic relationship matrix). The model incorporates relative census size and so can model the potential effects of drift. Moreover, despite the complexity of the calculations involved, Relethford has developed software (RMET 5.0) that makes this analysis relatively straightforward and produces both genetic distance estimates and F_{ST} , a commonly used statistic for reporting among-group variation. Among studies of dental metric variability within the cemetery, there is no clear preferred statistical approach and the choice of statistic is in large part dependent on the dimension of population dynamics being investigated: kinship and cemetery structure, postmarital residence, sample aggregate phenotypic variability, temporal microchronology, and age-structured phenotypic variation. As a result of methodological innovations, there has been a notable surge in both inter- and intracemetery studies of dental metric data since the 1990s.

A variety of issues must be addressed before dental metric data from archaeological sites can be used for multivariate analysis. Tooth size is known to be influenced by sex (see below), and so researchers must either separate their data for males and females, transform their data, or assume equal proportions of males and females in the dataset. Many scholars also scale the metric data for each skeleton by the geometric mean of each individual in order to increase sensitivity to shape differences (as opposed to simply tooth size). Individual tooth rescaling and many other aspects of multivariate approaches to dental metric analysis require complete datasets (data for each variable from each individual in the analysis). Thus, researchers commonly estimate or impute missing data using methods included in available statistical software packages. Prior to any data estimation, variables and individuals with a high number of missing values are culled from the dataset. Metric variables may also be removed when they demonstrate correlation with

age-at-death, presumably due to a dental wear effect.

The most recent comprehensive research on global dental metric variability and population history demonstrates results similar to those obtained in studies of genetic and craniometric variability, including evidence for the greatest level of intraregional population variability in sub-Saharan Africa (Hanihara 2013). Larger tooth size is the ancestral condition in humans and tooth size reduction has been attributed to relaxed selective pressure for large teeth following changes in food processing techniques and other cultural practices, especially in the last 10,000 years. The largest tooth sizes have been documented in Australia, followed by Melanesia, Micronesia, sub-Saharan Africa, and Native America. The smallest tooth sizes are found among some Southeast Asian populations, the Jomon/Ainu of Japan, and Western Eurasia. East/Southeast Asia and Polynesia demonstrate intermediate tooth size.

The measurement of teeth is also used to estimate sex, although this approach is generally not widely utilized by bioarchaeologists because better methods exist (Teschler-Nicola and Prossinger 1998). Male teeth tend to be larger than those of females and most studies point towards the canine (especially the mandibular canine) as the most sexually dimorphic tooth. However, the difference in tooth size between the sexes is not marked and single measurements or indices based on single tooth measurements have had mixed success for estimating the sex of skeletons. Better results have been demonstrated for multivariate discriminant functions that include measurements from both maxillary and mandibular teeth. One of the limitations for estimating sex based on dental measurements in archaeological samples is that differences in tooth dimensions vary among populations. Thus, indices or discriminant functions for sex estimation based on dental measurements must be specific to the archaeological population under investigation.

Although variability in tooth dimensions among individuals is largely attributable to genetic factors, environmental influences can also have an effect, including poor nutrition, chronic illness, and other developmental disruptions (Larsen 2015, 26–29). In a number

of bioarchaeological studies, researchers have attributed a relatively quick diachronic reduction (or enlargement) of tooth size to a change in health status, particularly following subsistence shifts from foraging to farming. Scholars have also compared permanent tooth dimensions of individuals who died as children to those of adults to test the hypothesis that the skeletons of children represent individuals who suffered from greater physiological stress during childhood as compared to those members of society that survived into adulthood. In other studies, researchers have examined fluctuating asymmetry in tooth dimensions as a possible tool for identifying individuals and populations that suffered from poor diet and health. The results of such studies have been mixed and a useful direction of future research would be to test whether elevated evidence for asymmetry corresponds with other measures of physiological stress in human skeletons.

Diagenesis of Bone

IAN SCHARLOTTA

Aix Marseille Univ, CNRS, Minist Culture & Com,
LAMPEA, Aix-en-Provence, France

Bone is perhaps the single greatest potential data source for archaeological and paleontological information. Skeletons are composed of an organic-mineral composite material that carries macro-, micro-, and nanoanalytical scale behavioral information. Different skeletal elements contain variable proportions of organic and mineral matrices. Bone, enamel, and dentin/ivory all contain bioapatite, a mineral similar to hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), within a fibrous protein matrix (comprising 90% of organic content), composed primarily of collagen (see DENTAL DEVELOPMENT and HUMAN GROWTH AND DEVELOPMENT). The mineral type, microstructure, crystal size, mineral lattice tightness, and purity of bioapatite vary based on the skeletal element and individual life history. Differences in formation processes, chemistry, and structure allow for the incorporation of minor and trace elements into lattice flaws, and ionic substitutions within the mineral matrix (see DIET AND TRACE ELEMENTS). Histories of health and diet are integrated into bones and teeth via stable isotopes and trace elements (see DIET AND CARBON ISOTOPES; DIET AND NITROGEN ISOTOPES; and DIET AND SULFUR ISOTOPES), as are provenance and mobility through geochemical tracers (see HUMAN SKELETAL GEOCHEMISTRY; MOBILITY AND LEAD ISOTOPES; MOBILITY AND OXYGEN ISOTOPES; and MOBILITY AND STRONTIUM ISOTOPES), geologic age (see URANIUM-SERIES), and environmental conditions (see ENVIRONMENTAL ARCHAEOLOGY; GEOARCHAEOLOGY; and MICROARCHAEOLOGY). In order to accurately reconstruct biological, behavioral, or environmental paleo-records, skeletal materials must either be an intact record of events during life or have undergone known physical and chemical

processes that can be accounted for during analysis.

Taphonomy

Taphonomy is concerned with any changes that can occur between the time of death and the recovery of a bone. There are two general categories: biostratinomy, or the effects prior to final deposition, and diagenesis, or post-depositional effects. The alterations of bone addressed by the field of biostratinomy can include, but are not limited to, digestion, trampling, exposure, butchering, defleshing, cooking, burning, and deliberate burial (Millard 2001). Many of the physical and chemical changes incurred during this stage will determine the progression of subsequent diagenetic changes. Diagenesis is a complex process that is site-specific, often localized, and not linearly related with burial time. It is controlled by different intrinsic factors of the tissue specimen, such as its size, porosity, and chemical and molecular structure, as well as by extrinsic external factors such as microbial load, temperature, humidity, hydrology, pH, and redox conditions of the burial environment but also the skeletal tissue itself. Diagenetic pathways in bone, dentin, and enamel and their organic (collagen and other structural proteins) and inorganic (bioapatite) components vary markedly because of their chemical and structural differences. Localized manifestations of different diagenetic processes will generally follow external points of entry such as physical cracks and foramina in the bone cortex.

In addressing the complex interactions involved between bone and external factors, important questions include: what is changing, how is it changing, where are changes occurring, and how will changes alter analysis and/or data recovery efforts? Diagenetic effects take place within bone tissues, in pore spaces and cavities between components, and in the surrounding sediment. Alteration of the bone is governed by the stripping or ionic substitution

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0182

of bioapatite with other minerals. Pore spaces and trabeculae can fill with diagenetic materials that reflect changes in burial matrix and/or location through time. Bioapatite crystals in enamel are an order of magnitude larger than in bones, limiting pore spaces and diagenetic alterations. Dentin/ivory has pore spaces akin to enamel, but organic matrices like bone prior to degradation. The burial matrix affects the outer surfaces (e.g., crusting, coating, stripping), the nature of groundwater (both its chemical make-up and transportability), and whether buried bones are crushed or deformed based on the presence/absence of diagenetic cements in the sediments. The after-effects of salt and sediment movement are more prevalent in marine contexts, but have the same considerations of exposure, physical changes, and solubility potentials.

Diagenesis to the organic phase of bone

Diagenetic changes can be broadly identified as organic, inorganic, and microbial processes. Organic diagenesis involves the decay/loss of protein (e.g., collagen, osteocalcin). Any attempt at radiocarbon dating, aDNA, amino acid racemization dating, or lipid survival will inevitably entail assessment of organic diagenesis. The stability of bones lies in the link between interwoven protein fibers, reinforced by crystalline matrices that form along the fibers. The degradation of the organic phase by microorganisms leaves the inorganic phase susceptible to chemical degradation. Recovering collagen and other proteins from archaeological samples is not difficult; the problem is determining what is left and what useful information it contains. The decomposition history of extractable proteins demonstrates that the biggest source of diagenetic effects is humic substances (complex acids formed from decomposing organic matter) moving from soil to bone during burial, where these substances can chemically link to collagen, affecting its isotopic composition. Experimental studies (van Klinken and Hedges 1992) found that humic acids react rapidly with collagen and that some standard chemical treatments do not entirely remove them, leaving changes that alter collagen to the extent of providing unreliable

isotopic measurements that can only be detected by a combination of measurements (i.e., C/N ratio, amino acid composition, and infrared spectroscopy).

Collagen survival is greatly dependent upon temperature and humidity, limiting the ability to conduct archaeological science studies on bones from warm and humid burial environments (e.g., jungles) where decomposition occurs rapidly and humic substances are abundant. Proteins can escape degradation by chemical or microbial attack when physically encapsulated in networks of soluble soil organics (e.g., tanning processes, compost, and peat bogs). Survivability lies in the complex molecular structure, where the bonds that stabilize the molecule at each level must break for the protein to “unfold” and expose sites for degradation. Collagen is the dominant protein, though other proteins (e.g., osteocalcin) can bind to minerals and survive in smaller fragments for millennia. However, experimental recovery efforts have shown that once collagen is degraded, other proteins will also be too degraded to hold useful biological information.

Microbial activity, which includes fungi, bacteria, and composite mixtures of organic and inorganic molecules, begins very shortly after death, frequently taking over a body within hours. Microbial activity begins with soft tissues, but rapidly progresses to bones, modifying both organic and inorganic phases, creating histological changes within months of deposition. The first descriptions of microbial activity on mineralized tissue were published in 1864 by C. Wedl, finding 8- μm -diameter tunnels in sections of teeth exposed to untreated well water and in fossil reptile teeth; this type of tunneling was defined as Wedl or centrifugal tunneling (Jans et al. 2004).

Three other types of microbial damage (linear longitudinal, budded, and lamellate) all appear to be caused by bacteria. These types of microscopic focal destruction can be distinguished histologically by morphology (size and shape), the presence of mineralized edges along degraded microbial tunnels, and the presence of abnormally sized crystal structures (e.g., plates). Bacterial action is prevalent under most environmental conditions, though waterlogged terrestrial sites often yield very well-preserved bone, indicating that the agents of change require an aerobic environment. Microbial activity leaves

very distinct traces within the bone matrix and the changes that are discrete and visible on histological slides.

Diagenesis to the inorganic phase of bone

Diagenetic changes in the mineral phase occur due to the damage and loss of mineral through dissolution or chemical erosion. Materials are transported and recrystallize elsewhere. Precipitation of new material can occur, or the incorporation of foreign materials into existing mineral matrices through ion uptake, or diffusion, from intrusive solutions. A third process can also occur, where a combination of loss and gain leads to internal changes of the mineral matrix to a form that differs from the original bioapatite, changing its chemical composition and structure. Dissolution is the primary operator for any mineral loss in a bone, though weight loss and porosity increases can be attributed to the loss of the organic phase.

The presence of collagen ensures the stability of the mineral matrix; thus, the ultimate source of crystallinity change is in the microbial and organic diagenetic effects that affect collagen, yet the resulting changes are part of inorganic diagenesis. Once collagen is lost, charged foreign ions are likely to take up residence within pore spaces. If the original crystalline structure of the bioapatite matrix is altered, the result is generally increased crystal size or crystallinity. Crystallinity of bone is also affected by uptake of fluorine (F^-), intrusive carbonate (CO_3^{2-}), and the transformation of bioapatite into other minerals (e.g., francolite or brushite). The rate at which changes can occur within the inorganic phase is governed by the chemical reactivity of the groundwater that can penetrate bone during burial.

Mature compact bone is comprised of lamellae traversed by individual osteons (Haversian systems). Haversian systems form by cutting through preexisting bone, growing new layers around the central Haversian canal, leaving discrete onion-like layers of bone that are separated from the surrounding tissues by a thin protein membrane (cement line). This cement line prevents the passage of material between Haversian systems except via the canals linking

osteocytes (mature bone cells). Internal bone water is generally sufficient to maintain a closed chemical system that requires the diffusion of ions either in or out, through internal canals (Hedges 2002). Diffusion or the penetration of diagenetic effects is limited to solutions within these canals, and areas physically exposed by degradation. Bone matrix within older osteon layers can thus remain unchanged until the process of bone turnover ruptures/replaces the osteon itself.

Analytical methods for identifying bone diagenesis

Microanalytical techniques for mapping and in situ analyses of elemental concentrations have become increasingly important means for assessing the extent of diagenetic alteration, reconstructing the burial environment through time, identifying diagenesis-resistant portions of bones, and reconstructing archaeological behaviors (see *ARCHAEOOMETRY* and *MICROARCHAEOLOGY*). Elemental concentrations of Sr, Zn, and Br, and Sr/Ca, Ba/Ca, and Mg/Ca ratios indicate provenance and to a lesser degree diet (see *DIET AND TRACE ELEMENTS*). Diagenesis can be approached with different analytical goals in mind: study of the diagenetic processes involved; alterations and subsequent effects on analytical chemical data recovery; comparative efficacy of different analytical methods in light of suspected diagenetic alterations; or specific focus on reconstruction of changes in the burial environment through time, as evidenced by diagenetic alterations.

To characterize and quantify diagenetic processes and their influence on the structural and chemical integrity of bones and teeth many different techniques can be applied. Studying internal structures (histology) and mapping elemental distributions uses cathodoluminescence and scanning/transmission electron microscopy (SEM/TEM). Identifying elemental additions/subtractions includes isotope ratio (IR) and inductively coupled plasma (ICP) mass spectrometry, particle-induced X-ray/gamma-ray emission (PIXE/PIGE), and X-ray fluorescence (XRF). Mineralogical, molecular, structural,

and compositional changes are identifiable using Rutherford (elastic) backscattering, X-ray diffraction (XRD), Hg-intrusion porosimetry, computerized tomography (CT), or Raman and Fourier transform infrared spectroscopy.

Current research is establishing internally verifiable analytical data for diagenetic alterations within bone samples. Verification that microfocal diagenetic effects are not biasing results employs correlations between individual osteons (Scharlotta, Goriunova, and Weber 2013) and variability within bone samples. Laser ablation, microprobe, and other microsampling methods will be important in future studies as chemical variability between different skeletal elements will help to identify diagenetic process, burial histories, and biogenic behavioral data using the same analyses.

FURTHER READINGS

Diet and Carbon Isotopes

ERIC J. BARTELINK

California State University, Chico, USA

The element carbon has two stable isotopes, ^{13}C and ^{12}C , which are incorporated into a plant's tissues in varying amounts depending on the specific photosynthetic pathway a plant has evolved to use (C3, C4, or CAM). For chemical reactions such as photosynthesis that do not go to completion, the product will incorporate different amounts of the heavy and light isotopes compared with the original substrate due to isotopic fractionation (Fry 2006).

The most abundant isotope of carbon (>99%) in the atmosphere is ^{12}C , with ^{13}C and ^{14}C comprising less than 1%. Carbon-14 is a radioactive isotope that is useful for dating organic remains less than 60,000 years in age (known as radiocarbon dating). It is not considered further here because it does not provide information on diet. Stable carbon isotopes are measured using isotope ratio mass spectrometry (IRMS) (see MASS SPECTROMETRY (MS)) and are reported as the ratio of ^{13}C to ^{12}C compared with an international standard of known composition. Stable isotope ratios are reported in parts per 1000 difference relative to the standard, known as a per mil (‰). Once an isotope ratio is converted to a per mil value, the delta symbol (δ) is used to report the value (e.g., $\delta^{13}\text{C}$, "delta carbon-13"). The use of the per mil value is simply to convert a small value with multiple decimal places to a whole number for ease of comparison. Stable carbon isotope ratios are reported using the following equation:

$$\delta^{13}\text{C} = \frac{{}^{13}\text{C}/{}^{12}\text{C}_{\text{sample}} - {}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}}{{}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}} \times 1000(\text{‰})$$

The International Atomic Energy Agency (IAEA), and for the USA the National Institute of Standards and Technology (NIST), have

identified appropriate international reference standards to ensure accuracy and comparability in reporting stable isotope results. Precision for carbon isotopes is within 0.1‰ for most IRMS.

The carbon isotope standard is Pee Dee Belemnite (PDB), a Cretaceous Period marine fossil limestone (*Belemnitella americana*) from the Pee Dee Formation in South Carolina. PDB was chosen as a standard because it contains more ^{13}C than almost all lifeforms. Because the original PDB standard has been exhausted, it is recommended that researchers use the updated Vienna-PDB standard (VPDB), which has been calibrated to the original standard. In-house standards are also used by stable isotope laboratories to ensure accuracy and reliability of measurements. By definition, VPDB is assigned a value of 0‰. This results in negative isotope values in organisms because their tissues have less ^{13}C than the standard.

Carbon fixation is the process by which organisms convert inorganic compounds, such as carbon dioxide (CO_2), to organic compounds. Photosynthesis is a prime example of carbon fixation. Three different photosynthetic (metabolic) pathways have evolved for fixing carbon: C3 (Calvin-Benson photosynthetic pathway); C4 (Hatch-Slack photosynthetic pathway); and CAM (crassulacean acid metabolism). These different photosynthetic pathways account for isotopic variation among plants within terrestrial ecosystems. The majority of the Earth's vegetation (~95%) is composed of C3 plants such as grasses, trees, shrubs, and legumes (common sources of fruits, vegetables, beans, and grains). These plants use a 3-carbon molecule and discriminate against ^{13}C during photosynthesis. This results in $\delta^{13}\text{C}$ values that average $-26.7 \pm 2.7\text{‰}$ (Cerling, Ehleringer, and Harris 1998). C4 plants use a 4-carbon molecule and discriminate less against ^{13}C during photosynthesis compared with C3 plants. This results in higher $\delta^{13}\text{C}$ values that average $-12.5 \pm 1.1\text{‰}$ (Cerling et al. 1998). C4 plants are often tropical grasses found in hot, arid environments, and include cultigens such as

maize, millet, sorghum, amaranth, and sugarcane (representing less than 5% of Earth's vegetation). CAM plants fix carbon using both a C3- or C4-like pathway, and therefore have values that often overlap with these plant types. These include desert-adapted plants such as succulents and cacti. Finally, carbon isotope values in marine ecosystems overlap isotopically with C4 plants due to the ^{13}C -enriched sources of carbon in the ocean (e.g., dissolved bicarbonate). The carbon isotope signatures from plants and sources of marine carbon are passed into animals, including humans, with little fractionation between trophic levels ($<1\%$). Stable carbon isotopes in bones and teeth thus reflect the sources of dietary carbon.

Applications of carbon isotopes within anthropology are diverse, and generally provide complementary lines of evidence to areas such as zooarchaeology (see ZOOARCHAEOLOGY AND HUMAN DIET RECONSTRUCTION and ZOOARCHAEOLOGY AND STABLE ISOTOPES), paleoethnobotany (see PALEOETHNOBOTANY AND STABLE ISOTOPES), food residue analysis (see FOOD RESIDUE ANALYSIS), and trace element analysis (see DIET AND TRACE ELEMENTS). They have been used to reconstruct diet among both modern and earlier human societies, ancient hominins (e.g., australopithecines and Neandertals), and also living and ancient nonhuman primates. Other applications include the analysis of archaeofaunal and archaeobotanical remains to reconstruct past foodwebs and to study environmental change.

Bone is composed of both inorganic and organic components, comprising about 70% and 30% of dry bone weight, respectively. The inorganic component found in bone is a mineral known as hydroxyapatite (referred to as "bioapatite"). More than 85% of the organic component of bone represents collagen, with the remainder comprising other proteins and lipids. Because bone tissue continuously remodels throughout life, bulk carbon isotope values reflect several years of diet (ca. 5–20 years, depending on the remodeling rate of the bone sampled). Tooth dentin is also composed primarily of both collagen and hydroxyapatite, whereas enamel is nearly 100% hydroxyapatite. Isotope signatures are incorporated into these

structures at the time the tooth formed (e.g., infancy and childhood), and do not remodel during life. Carbon isotopes of bone collagen and the carbonate in bioapatite have featured prominently in the bioarchaeological literature (see BIOARCHAEOLOGY), and have focused on important topics such as agricultural transitions (e.g., introduction of maize in the eastern US), the exploitation of marine resources by coastal and island societies, and how dietary macronutrients are differentially incorporated into bone and dentinal collagen versus bone and tooth bioapatite. In conjunction with nitrogen isotopes (see DIET AND NITROGEN ISOTOPES), carbon isotopes provide a powerful tool for reconstructing paleodiet.

The 1980s were marked by debates on whether carbon isotopes of bioapatite could be used to reconstruct the diets of ancient animals, including humans. The debate centered on two issues—one dealing with postmortem preservation of bioapatite, and the other relating to the information that can be gleaned from carbon isotopes of bioapatite versus collagen. Sullivan and Krueger (1981) argued that carbon isotopes of bioapatite could be used to reconstruct diet of ancient fossilized remains that showed complete collagen degradation. This is important because the method has the potential to extend dietary analysis to skeletal material that is thousands or even millions of years old. However, Schoeninger and DeNiro (1982) argued that postmortem mineral exchange between skeletal remains and the burial environment alters isotope values, rendering them meaningless. This issue has been overcome in part by identifying appropriate treatment protocols for removing contaminants from samples, as well as the development of new methods for screening samples for postmortem alteration. The second issue has been clarified through a series of controlled animal feeding studies on rodents (Ambrose and Norr 1993; Tieszen and Fagre 1993). These studies have found that carbon isotopes of bone collagen are biased toward the sources of dietary protein (a protein routing model), whereas the carbonate in bioapatite reflects the incorporation of all dietary macronutrients, or the whole diet (i.e., carbohydrates, fats, and protein not used to synthesize collagen). These studies found that bioapatite $\delta^{13}\text{C}$ values are approximately

+9.4‰ higher than that of the whole diet, and that collagen $\delta^{13}\text{C}$ values are approximately +5.0‰ higher than the source of dietary protein. However, spacing between the collagen and dietary protein $\delta^{13}\text{C}$ varies depending on whether the source of dietary protein is *more* or *less* enriched in ^{13}C compared with the $\delta^{13}\text{C}$ of the whole diet. More recent studies of published datasets have resulted in the development of a simple carbon isotope model (Kellner and Schoeninger 2008). A more recent revised model by Froehle, Kellner, and Schoeninger (2010) uses two regression lines to define C3 versus C4/marine protein diets, as well as C3 versus C4 whole diets. Isotope data from humans and other animals can be plotted against the model to identify not only the source of dietary protein, but also the nonprotein macronutrients (i.e., carbohydrates and fats). These developments have provided exciting new avenues from which to explore dietary variation in ancient and modern animals.

A major limitation of stable isotope analysis on ancient skeletal remains is the potential for postmortem alteration of bones and teeth. Diagenesis (see **DIAGENESIS OF BONE**) refers to postmortem chemical alterations that result from the interaction of skeletal remains and groundwater and soil from the burial environment. Over time, chemical exchange can result in postmortem alterations to stable isotope values as well as trace element concentrations. This is especially problematic for poorly preserved remains from tropical regions and for partially or completely fossilized remains (e.g., ancient hominin fossils). Carbon isotope measurements on bones and teeth that are significantly altered are often unreliable. Paleoanthropologists, bioarchaeologists, and archaeologists must take great care to evaluate sample integrity and to compare data on ancient samples with modern baseline data to ensure that results are tracking the biogenic isotope signatures. Collagen sample quality indicators, such as the percent collagen yield and atomic C/N ratio, are usually effective for identifying samples affected by diagenesis. For bioapatite, Fourier transform infrared spectroscopy (FT-IR) is a common tool for identifying samples that show low carbonate content,

evidence of recrystallization, or the incorporation of other contaminants from the burial environment.

Diet and Nitrogen Isotopes

TAMSIN C. O'CONNELL

University of Cambridge, UK

Nitrogen isotopic analysis as a method of dietary assessment is now widely used in archaeology. Since the 1970s, it has been observed that individuals have a higher nitrogen isotopic ratio ($^{15}\text{N}/^{14}\text{N}$) than their diets, and that this pattern holds true for all types of mammals, birds, fish, reptiles, and insects. Thus, the technique is used to identify the trophic position of an individual within the food chain. In archaeology, particularly for the study of human diet, this has often taken the form of distinguishing whether humans are more carnivorous or herbivorous, using the nitrogen isotopic value as a proxy for the proportion of animal versus plant protein consumed.

Underlying mechanisms

Nitrogen is a key chemical element for all organisms, as it is a fundamental part of amino acids, the molecules that are the building blocks of proteins, which themselves are the primary constituents of body tissues and metabolites (bones, muscles, skin, organs, blood). For plants, nitrogen is taken up from the soil in a variety of forms, synthesized into amino acids, and then formed into proteins (Robinson 2001). For animals, the source of nitrogen is dietary protein, which can be a limiting factor in growth and tissue synthesis.

Nitrogen exists as two stable isotopes (see ISOTOPES) which have the same electronic and proton configuration, but a different number of neutrons—the common form, ^{14}N , has seven neutrons, and the much rarer ^{15}N has eight neutrons. The resulting mass difference between the

two isotopes means that chemical reactions occur at slightly different rates, which causes variations in the $^{15}\text{N}/^{14}\text{N}$ ratio (expressed as $\delta^{15}\text{N}$) between reactant and product. This isotopic effect, known as fractionation, may occur in physical, chemical, or biological processes throughout the biosphere, and results in significant differences in nitrogen isotopic ratios in different parts of the biosphere.

A wide range of observational studies have shown that consumers have higher nitrogen isotopic values than their diets, and for each step in the food chain (plant to herbivore, herbivore to carnivore, etc.) there is an approximate 3–5‰ increase in $\delta^{15}\text{N}$ value—the “trophic level enrichment” (Hedges and Reynard 2007). The underlying mechanism is as yet poorly understood, though it is likely related to amino acid transamination and extensive nitrogen cycling within the body (Schoeller 1999). Controlled studies have shown that diet is the primary influence on body nitrogen isotopic values, but environmental and physiological factors can also have an effect. The trophic level enrichment is quite variable under a range of environmental and climatic conditions (temperature, altitude, aridity), as well as being affected by physiological factors such as water stress, starvation, and growth, and diet macronutrient composition (Boecklen et al. 2011; Makarewicz and Sealy 2014). The magnitude of these influences is unknown, because the metabolic origin of the ^{15}N enrichment between diet and body is unclear. However, general trends are that stress (water stress, heat, starvation) elevates $\delta^{15}\text{N}$, whereas growth depresses $\delta^{15}\text{N}$ values. Studies have also shown that individuals are not isotopically homogeneous—that different tissues within an individual have different nitrogen isotopic values, and that different amino acids within proteins vary in their $\delta^{15}\text{N}$ values (Boecklen et al. 2011). These patterns emphasize that nitrogen metabolism within heterotrophic organisms (including animals) is complicated—a point that is frequently overlooked in the use of the technique.

What can we analyze?

In archaeology, three key sample categories are analyzed, all of which are proteinaceous tissues containing nitrogen: bulk tissues such as bone collagen or tooth dentine; serially sampled tissues, such as hair or tooth dentine; and individual amino acids from body proteins. Each tissue represents a different time-slice of an individual's diet, depending on growth period and turnover rate: bone with its slow turnover integrates long-term diet, hair provides a linear record of short- to medium-term diet, and teeth record a snapshot of childhood diet consumed during their formation period. Sequential analyses of hair can show dietary change over a timescale of months, as can the subsections of tooth dentine, though the question of temporal resolution in dentine subsections has not been fully elucidated. Individual amino acid isotopic analysis is in its early stages, but appears to show clear signals of trophic level change when comparative data from potential food resources are limited or unavailable (Makarewicz and Sealy 2014). It has the significant advantage that analysis of multiple amino acids increases the dimensionality of the data—we are not trying to reconstruct the full complexity of diet from one or two measured parameters. Sometimes, multiple tissues are combined for a full life-history approach, with different samples from the same individual analyzed to gain a finer-grained assessment of diet (e.g., childhood versus adult diet). Key in all studies of archaeological material is a consideration of diagenesis (see *DIAGENESIS OF BONE*)—to ensure that the data measured are biogenic, and not altered postmortem. Furthermore, sample preparation and analysis must be appropriate, with due reporting of the necessary information to allow an assessment by others of sample and data quality (Lee-Thorp 2008).

Interpretations

Nitrogen isotopic values in archaeological collagen, together with carbon isotopic data (see *DIET AND CARBON ISOTOPES*), provide a direct measure of the diet of an individual. When used

as a quantitative method of diet reconstruction, the technique relies on comparing the nitrogen isotopic values of the consumer to that of potential dietary resources (thus considering relative not absolute values), factoring in the expected isotopic offset between diet and body (Hedges and Reynard 2007). Unlike for carbon isotopic values, the nitrogen in our bodies can only be derived from dietary protein, so nitrogen isotopic values tell us about protein sources, and not carbohydrate or fat intake. This must be remembered as plant foods usually have lower proportions of protein than animal sources, and so will contribute proportionally less dietary protein from the same dry weight. Another caveat is that primary and secondary animal proteins are usually indistinguishable using nitrogen isotopic data (e.g., a cow's meat and milk will be isotopically similar).

Isotopic analysis can be used to great effect in paleodietary reconstruction, but there is a high likelihood that we will never be able to calculate exact percentages of foods consumed: there are too many variables. Poor comprehension about the current unknowns (e.g., metabolic underpinnings, natural variation)—as well as a lack of scientific rigor—is responsible for many of the poorly executed studies in paleodietary reconstruction (see discussions in Makarewicz and Sealy 2014). By acknowledging the constraints of the technique, and by attempting to explore and not to ignore them, we can utilize the method to its best advantage.

Interpretation of diet from nitrogen isotopic data is always best carried out in conjunction with all other available archaeological, isotopic, and chemical evidence (see *DIET AND CARBON ISOTOPES*; *DIET AND SULFUR ISOTOPES*; *DIET AND TRACE ELEMENTS*; *ZOOARCHAEOLOGY AND HUMAN DIET RECONSTRUCTION*; *PALEOETHNOBOTANY AND STABLE ISOTOPES*; *PALEOETHNOBOTANY*; and *FOOD RESIDUE ANALYSIS*). Increasingly, inferences are drawn from the data using some form of modeling, Bayesian or otherwise, in order to constrain potential interpretations (Boecklen et al. 2011; Makarewicz and Sealy 2014).

Applications

Applications of nitrogen isotopic analyses in archaeology have addressed a range of questions about human diet in the past, including dietary composition, nutritional adequacy, social and cultural habits, and practices of child-rearing (concerning pregnancy and infant feeding), as well as plant and animal husbandry.

Neanderthal specimens from Belgium and Croatia have been found to have $\delta^{15}\text{N}$ similar to contemporary large carnivores such as wolf, hyena, and cave lion, providing quantitative support for the belief, based on other archaeological evidence, that Neanderthals were efficient large-game hunters in the cold environment of Paleolithic Europe. However, the precision and resolution of this interpretation has been questioned (Lee-Thorp 2008; Schoeninger 2014).

A key application is the identification of marine foods in the diet, as they typically have much higher nitrogen isotopic values due to the longer length of marine food chains. Such analyses have been used in coastal, lake, and river settings from the Paleolithic to post-medieval times, often in conjunction with other evidence, at both bulk protein and individual amino acid levels (Lee-Thorp 2008; Schoeninger 2014). Such work has demonstrated the importance of whaling to protohistoric Thule people in the Canadian Arctic, and showed that Mesolithic humans along the northwest coast of Europe and the Jomon people of Japan were strongly dependent on fish. Fish consumption, identified by high nitrogen isotopic values of bone collagen, tallied with other evidence for status and mobility in medieval clergy at Whithorn Cathedral Priory in Scotland. Recent work on the fish remains themselves has used nitrogen isotopic data as a proxy for fish provenance, tracing the medieval cod trade across the North Sea, which correlates with isotopic evidence for increased fish consumption in Anglo-Saxon England around this time.

Although mobility is often addressed using other isotopic systems (e.g., see *MOBILITY AND LEAD ISOTOPES*; *MOBILITY AND OXYGEN ISOTOPES*; and *MOBILITY AND STRONTIUM ISOTOPES*), nitrogen isotopic evidence for dietary change has been used as a proxy for movement, both by

comparing different skeletal elements, such as in African slaves taken across the Atlantic to work on Barbadian sugar plantations, and by assessing sequential change, for instance the clear isotopic shifts along the hair shafts of Inca child sacrifices in the Andes (see references within Makarewicz and Sealy 2014).

The identification of infant feeding (see *INFANT FEEDING*) and weaning has been widely tackled across many human groups using nitrogen isotopes (following the logic that infants are effectively eating their mothers, so should be one trophic level higher), but this area is not as simple as is often assumed, frequently leading to inconclusive results (Reynard and Tuross 2015). Nutritional and physiological stress is another problem that likely causes nitrogen isotopic change, but is potentially invisible depending on samples analyzed: for instance, modern women showed a decrease in hair $\delta^{15}\text{N}$ values during pregnancy, but this was not visible in bone collagen analyses of post-medieval individuals of known parity from St Mary Spital in London. However, work on serial sections of tooth dentine has identified clear signals of both dietary and nondietary changes in Irish potato famine victims.

The agricultural practice of manuring is visible in the nitrogen isotopic values of archaeological cereal grains, since adding isotopically enriched nitrogen to soils in the form of animal manure increases the nitrogen isotopic values of plants (Styring et al. 2015). However, nitrogen can be added in other forms (such as plant-based green manures) that do not necessarily increase plant nitrogen isotopic values. Furthermore, nitrogen turnover rates in the soil can be very protracted, so soil fertilization does not necessarily have a clear nitrogen isotopic signature visible in crops. Single amino acid analyses of plants are showing some promise in this direction.

Diet and Sulfur Isotopes

ASTA J. RAND

Memorial University of Newfoundland, Canada

OLAF NEHLICH

University of British Columbia, Canada

Dietary preferences and subsistence practices are socially mediated and depend upon environmental and ecological settings. Thus, the study of ancient nutritional patterns provides insight into past sociocultural processes. This has traditionally been explored using stable carbon (see DIET AND CARBON ISOTOPES) and nitrogen (see DIET AND NITROGEN ISOTOPES) isotope analysis ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, respectively) from archaeological tissues. The analysis of stable sulfur isotopes ($\delta^{34}\text{S}$) offers a novel method for investigating the dietary practices of past populations (Nehlich 2015). The $\delta^{34}\text{S}$ values of terrestrial and aquatic ecosystems generally differ as a result of variation in the chemical incorporation of sulfur into bio-molecules. Furthermore, sulfur availability and reactivity vary micro-regionally and influence local sulfur isotope values in the biosphere. Thus, the $\delta^{34}\text{S}$ values of archaeological bio-remains (e.g., bones, hair, teeth, nails, pottery residues, etc.) may identify the source of dietary proteins when the sulfur compositions of different ecosystems within an area are sufficiently divergent.

Principles of stable sulfur isotope analysis

In stable isotopic analysis, mass spectrometry (see MASS SPECTROMETRY (MS)) measures the ratio of the two most abundant stable isotopes in a sample against a known ratio in a standard reference material, which is reported using the

delta notation (δ) in per mil units (‰). Thus, stable sulfur isotope analysis measures the ratio of ^{32}S (95.02%) to ^{34}S (4.22%) relative to that of a standard as follows:

$$\delta^{34}\text{S}_{\text{VCDT}} = \left[\frac{(^{34}\text{S}/^{32}\text{S})_{\text{sample}}}{(^{34}\text{S}/^{32}\text{S})_{\text{standard}}} - 1 \right] \times 10^3 (\text{‰})$$

The natural standard, Cañon Diablo Troilite (CDT), is now depleted and an artificial Vienna Cañon Diablo Troilite (VCDT) scale has been established as the primary reference material for sulfur isotope analysis (Copelen and Krouse 1998).

Bioavailable sulfur in soils is derived from sulfates in groundwater, rain, atmospheric deposition, and, importantly, the underlying geology (Bern and Townsend 2008). Plants at the base of the food chain assimilate inorganic sulfates into their tissues by converting them primarily into methionine ($\text{C}_5\text{H}_{11}\text{NO}_2\text{S}$) and cysteine ($\text{C}_3\text{H}_7\text{NO}_2\text{S}$), but also minor sulfur-containing amino acids, with minimal fractionation (ca. $\pm 1.5\text{‰}$). As heterotrophic organisms, animals cannot produce methionine internally, and instead must obtain it from dietary protein with an average consumer-to-diet offset (fractionation) of $+0.5 \pm 2.4\text{‰}$ at each level of the food chain (Nehlich 2015, 6).

The concentration of biologically bound sulfurous molecules in organic tissues is highly variable, but relatively low. Both cysteine and methionine are present in human hair, whereas only methionine is present in bone collagen; thus, hair has a higher sulfur content (4.0 wt.%) relative to that of bone collagen (0.16 to 0.22 wt.%). Because organic tissues remodel over the span, they reflect the average $\delta^{34}\text{S}$ value of dietary protein consumed over specific time periods. For example, human hair grows at a faster rate than bone collagen is remodeled, and these tissues therefore reflect the average diet of the last several months and decades prior to death, respectively.

Sample preparation and analysis

The analysis of sulfur in archaeology (see *ARCHAEOLOGY*) initially focused on sampling human hair because the available techniques were complex and required large sample sizes. Improved preparation and online mass spectrometry technology now allow for routine sulfur isotope analysis of relatively small bone collagen samples (Richards, Fuller, and Hedges 2001).

Preparation of bone collagen samples for sulfur isotope analysis follows the same procedures used for stable carbon and nitrogen isotope analysis, although it has been suggested that an ultrafiltration step purifies the collagen, thus improving results (Nehlich and Richards 2009). Collagen is isolated through demineralizing in hydrochloric acid (HCl) and may then be treated with sodium hydroxide (NaOH) to remove humic contaminants prior to being gelatinized, filtered and freeze-dried. However, because relatively little sulfur is present in bone collagen, it is necessary to prepare larger samples (up to 1 g, depending on preservation) than for carbon or nitrogen isotope analysis.

Once prepared, approximately 10 mg of purified collagen is weighed into tin capsules with 1 mg of vanadium pentoxide (V_2O_5) to catalyze sample combustion. The resulting sulfur oxide (SO) and sulfur dioxide (SO_2) gases are reduced over hot copper to minimize the amount of sulfur trioxide (SO_3) produced, and are then channeled into an isotope ratio mass spectrometer (IRMS) for analysis.

Diagenesis (see *DIAGENESIS OF BONE*) chemically alters isotope values in bone collagen postmortem, causing them to no longer reflect biogenic isotope values accumulated during life. Therefore, sample integrity must be established prior to interpretation of $\delta^{34}S$ values from archaeological samples. To do so, it is also necessary to obtain carbon and nitrogen isotope data from the same samples so that the carbon, nitrogen, and sulfur contents (wt.% C, N, and S, respectively) as well as the ratios of sulfur to carbon and nitrogen (S:C and S:N, respectively) can be assessed. Samples that fall beyond acceptable parameters are considered diagenetically altered and must be removed from the dataset prior to interpretation (Nehlich and Richards 2009).

Applications of sulfur isotope analysis in archaeological research

Sulfur isotope analysis was initially employed to investigate ecological relationships in various environments (e.g., Krouse and Grinenko 1991). While its potential for addressing the limitations of carbon and nitrogen isotope analysis in archaeological studies of diet was recognized in the 1980s, the first applications of sulfur isotope analysis in archaeology were published in the 1990s.

Initial archaeological applications of sulfur isotope analysis focused on samples of human hair because it contains more sulfur-bearing amino acids than does bone collagen. The detailed study by Leach, Quinn, and Lyon (1996) demonstrated the utility of analyzing $\delta^{34}S$ values from ancient bone collagen for addressing questions of past human diets. Since then, numerous studies have examined $\delta^{34}S$ values from bone collagen in conjunction with other isotopic parameters and archaeological data to better understand past human dietary practices. This is necessary because sulfur isotope values represent dietary protein rather than the whole diet, thus making this method fundamentally interdisciplinary. Such studies have investigated the consumption of protein from different environments (marine, terrestrial, or freshwater), social dimensions of ancient diets (e.g., gendered difference in protein consumption; weaning practices), and the presence of nonlocal individuals interred at archaeological sites, as well as the ecological, economic, religious and other factors that influenced dietary preferences in the past.

The first studies to analyze sulfur isotopes in archaeological tissues were interested in identifying whether individuals consumed marine or terrestrial protein. This is possible because oceanic sulfate in marine ecosystems has a mean $\delta^{34}S$ value around +20‰ that is passed through the food chain to the consumers of marine protein. In contrast, $\delta^{34}S$ values in terrestrial and freshwater environments are much more variable (−20‰ to +20‰ and beyond, depending on the sulfur source). Importantly, elevated $\delta^{34}S$ values (i.e., >14‰) in consumer tissues were found not only to reflect a marine diet, but also a diet based on terrestrial coastal resources that adopt the isotopic composition of oceanic sulfate due to

the “sea spray effect”. This effect may extend up to 30 km inland, although this is dependent on climatic (e.g., wind direction) and topographic factors (e.g., mountains, plains, watersheds, etc.).

The differentiation of $\delta^{34}\text{S}$ values from aquatic and terrestrial diets is applicable in regions where the sulfur isotope compositions of these ecosystems are sufficiently distinct. When they are highly divergent, $\delta^{34}\text{S}$ values can more precisely identify and quantify dietary sources. Thus, baseline environmental sulfur compositions should be established using the $\delta^{34}\text{S}$ values of archaeological faunal remains. This is because, unlike with other elements (e.g., strontium (see MOBILITY AND STRONTIUM ISOTOPES) or oxygen (see MOBILITY AND OXYGEN ISOTOPES)), it is not possible to compare the $\delta^{34}\text{S}$ values of archaeological materials with those of modern ecological samples due to environmental pollution from fossil fuels.

Dietary change over the life history of an individual has also been investigated by comparing the $\delta^{34}\text{S}$ values from their bone collagen, tooth dentin, and sections of hair and nail. In general, such changes in diet have been associated with residential mobility when interpreted within specific environmental and archaeological contexts. Nonlocal individuals have also been identified when the $\delta^{34}\text{S}$ values of their tissues differ significantly from those expected in the local environment (based on either the average value of the sampled humans or that of possible food sources). Thus, stable sulfur isotope analysis complements other techniques by offering insights into dietary changes associated with migration in past populations.

Future directions for stable sulfur isotope analysis in archaeology

As the archaeological application of sulfur isotope analysis is relatively recent, there are many aspects that require further investigation. For example, within the last several years, the detailed evaluation of $\delta^{34}\text{S}$ data using advanced statistical methods has produced more comprehensive interpretations, especially when combined with conventional isotope data (e.g., $\delta^{13}\text{C}$, $\delta^{15}\text{N}$,

$\delta^{18}\text{O}$, and $^{87}\text{Sr}/^{86}\text{Sr}$). These evaluation techniques would also be beneficial in more sophisticated applications, such as the analysis of stable sulfur isotopes in individual amino acids or protein residues (see FOOD RESIDUE ANALYSIS).

However, the relatively large amount of sample required for analysis remains problematic. This is evident in several studies that assessed childhood diet by combining dentin from multiple teeth to obtain sufficient samples for stable sulfur isotope analysis. This is unfortunate, because teeth form at different ages, and combining the samples produced an averaged childhood $\delta^{34}\text{S}$ value. However, if the $\delta^{34}\text{S}$ values from samples of different teeth (which form at predictable ages) and bones (which remodel at varying rates) from the same individual could be analyzed, it would be possible to track dietary and residential changes throughout the life history of an individual in more detail.

Future research should also strive to conduct well-designed feeding studies to accurately demonstrate which components of different food sources (e.g., leaf, stem, root) are nutritionally relevant. Furthermore, the isotopic offsets between diet and the various tissues of different consumers must be securely established to produce reliable interpretations within small error margins.

Finally, there are several interpretative aspects that should be addressed in future studies. For example, animal and cereal plant proteins in the diet contribute roughly equal amounts of sulfur-containing amino acids to human tissues, whereas legumes and fruits contribute slightly less and nuts and seeds contribute slightly more (Young and Pellett 1994). Cultural practices will also influence the dietary contribution of sulfur; for example, traditional methods of processing maize with lime doubles the concentration of digestible methionine (Katz, Hediger, and Valleroy 1974), thus increasing the contribution of sulfur from this crop to the tissues of past peoples who prepared it in this manner. It is therefore important to further investigate the influence that foods with differing amounts of sulfur, and cultural practices that enhance food quality and availability of essential compounds, have on the isotopic sulfur composition of consumer tissues.

Diet and Trace Elements

ALEXIS E. DOLPHIN

University of Waterloo, Canada

Analyses of the trace element and/or stable isotope composition of human bones and teeth (and other tissues such as skin or hair) provide the most direct means for reconstructing the ancient diet (or paleodiet) of individuals and the populations of which they are a part. All members of *Homo sapiens* share a common chemical composition of their bones and teeth, yet there are some variations in skeletal chemistry that have been found to reflect differences in geographic origins, environmental exposures to pollutants, and the production, preparation, and consumption of foods. Trace elements from one's environment are incorporated into bones and teeth as they form during life, but may also be introduced in the burial environment. Bone is predominantly comprised of an organic protein component (collagen) and an inorganic crystalline mineral component (hydroxylapatite). Dental tissues, such as dentin and cementum, also bear significant organic components, while dental enamel, the hardest tissue in the human body, is composed of 96 percent hydroxylapatite. Trace element analyses of bones and teeth have focused primarily on sampling their inorganic component. The human body contains over 80 chemical elements, with many being necessary for various functions. Trace elements are present in very low quantities, and are usually measured in parts per million (ppm), or parts per billion (ppb), yet they have been found to vary in magnitude from individual to individual, and within bodily tissues in a single individual.

History

Variation in the trace element content of human hard tissues was first used to explore ancient diets during the early 1970s and 1980s when strontium

(Sr) was put forth as a possible indicator of relative meat consumption, or trophic level position in the food chain (Brown 1973). As a divalent and positively charged 2^+ ion, with an atomic size similar to that of calcium, strontium is able to substitute into the hydroxylapatite of bones and teeth during their formation. Other divalent ions such as barium (Ba) and lead (Pb) also substitute for calcium, although with less efficiency, due to their ionic size being greater than that of calcium. Even slight differences in ionic size relative to calcium result in a process known as "biopurification," whereby non-nutrient metal ions are preferentially removed from bone and tooth reservoirs with movement up the food chain (Elias, Hirao, and Patterson 1982; Burton 2008).

Despite the early promise of using trace elements to explore paleodiets, it was quickly recognized that human remains may be chemically altered or contaminated during their time in the burial environment (Sillen 1986; Hoppe, Koch, and Furutani 2003). This "diagenesis," or postmortem alteration, is the result of tissues reacting with soils and water during the period of burial. Diagenesis may involve the loss of "biogenic" elemental signatures, or those reflecting aspects of the individual's lifetime, and/or it may result from the addition of "diagenic" signatures reflecting contamination from the burial context itself. The degree of diagenesis varies not only from individual to individual but also from bone to bone, and even within bones. As a result, significant effort has been put into developing ways to assess the degree of diagenetic change, as well as means for removing contamination. Microscopic analyses examine the structural integrity of hard tissues, looking for signs of the physically and chemically disruptive presence of fungi, roots, mineral inclusions, bacteria, and so on. Fourier transform infrared (FTIR) spectroscopy or X-ray diffraction (XRD) is used by some researchers to identify whether the mineral component of bones and teeth has undergone significant diagenetic alteration. These techniques are used to produce a crystallinity index (CI), with a normal range of nondiagenetically altered crystallinity values

falling between 2.6 and 4.0 (Wright and Schwarcz 1996; Nielsen-Marsh and Hedges 2000). In addition, the presence of elements not typically found in uncontaminated bone, such as uranium or rare earth elements (REEs), can warn researchers that diagenetic alteration has likely occurred. A quantitative measure of the occurrence of diagenesis is possible through the measurement of a tissue's calcium/phosphorus (Ca/P) ratio. This ratio identifies the loss of the organic component in bone, and/or the addition of new minerals from the burial environment. Ca/P ratios of approximately 2.0 are considered indicative of unaltered hard tissues. If one or more of these approaches suggests that diagenesis has likely occurred, the bone or tooth samples may be chemically treated with a weak acid in order to attempt to remove diagenetic elements prior to conducting paleodietary analyses (Hoppe et al. 2003).

Not surprisingly, early studies of Sr and other trace elements, such as barium (Ba), zinc (Zn), copper (Cu), and magnesium (Mg), produced variable results, leading eventually to skepticism regarding the utility of trace elements for reconstructing paleodiets at all. This exploratory phase of trace element research demonstrated the importance of developing new models for interpreting trace element values, rather than assuming that all elements would vary simply and predictably with trophic levels (see key review publications by Buikstra et al. 1989; Ezzo 1994; Burton and Wright 1995; Burton and Price 2002; Burton 2008).

Today, researchers investigating ancient diets using trace elements take care to choose appropriate elements for analysis (those that are bone-seeking and may substitute for Ca in quantities that are measurable). They also recognize the need to develop an understanding of how elements vary in dietary components, how elements from dietary components interact within the body itself, and what factors may influence their uptake by bones and teeth (e.g., reproductive status, health, age, and the presence of other bone-seeking elements in the diet) given a particular archaeological and/or ecological context.

Key elements

The most commonly investigated trace elements for paleodietary reconstruction are Sr and Ba. Because both Sr and Ba are not required for any metabolic functions of the body, it is expected that their presence in bone and tooth tissues is only proportional to their presence in the diet during life (assuming diagenesis has been ruled out). Both of these elements are passed on from soils, to plants and hence to consumers, with discrimination against the uptake of Sr increasing with trophic level placement of the consumer (biopurification). The decrease in the Sr/Ca and Ba/Ca ratios with higher positions in the food chain has led researchers to equate low ratios with high meat consumption. This approach to investigating the degree of carnivory of consumers is, however, complicated by geological variability in soil chemistry and the fact that the research results are not consistently successful when attempting to use Sr/Ca and Ba/Ca ratios to elucidate intermediate trophic positions. Burton and Price (2002) argue that the theoretical foundation for using Sr/Ca and Ba/Ca to infer paleodiets is sound, but that simplistic interpretations equating certain values with meat consumption have proven to be misleading (Burton 2008).

Dozens of additional trace elements have been measured in bones and teeth since the first explorations of Sr variation. While some are used to reconstruct exposure to pollutants in the past, such as lead (Pb) or cadmium (Cd), the greatest focus has remained on paleodietary reconstruction—despite the fact that the ability of each element to indicate anything about past diets is often unclear. For example, because Zn is also a positively charged divalent ion, which can substitute for the Ca in bones in teeth, it has also received considerable attention by researchers interested in paleodietary reconstruction. The presence of Zn in bodily tissues has often been assumed to vary such that higher Zn/Ca ratios reflect greater meat consumption, or a higher trophic position. This assumption is based in large part on the observation that most body Zn is stored in muscle, and, as such, it might be reasonable to expect that someone who eats more muscle (meat) would demonstrate a higher Zn/Ca ratio in their own tissues. In the 1990s, it was

argued that Zn should not be used as a paleodietary indicator because, as an essential element, it is metabolically regulated in the gut (Ezzo 1994). More recent research, using dietary data collected from a living population of children in Mexico, found that Zn did vary with aspects of diet, but not with meat consumption. In this case, Zn/Ca ratios were found to vary with dietary quality (or bioavailability of Zn), rather than with any singular aspect of diet (Dolphin and Goodman 2009). Despite these complications, many researchers still erroneously use Zn as a simple paleodietary indicator based on the assumption that this element varies only by meat consumption.

Sampling and instrumentation

Sampling and analytical considerations vary depending on whether bone or tooth tissues are to be examined. The choice of tissue sample is also influenced by the nature of research questions regarding the timing of dietary shifts. Bone collagen and apatite are replenished every seven to ten years; thus the chemical signatures measured from bones reveal information about diets consumed during roughly the last decade of one's life. Each dental tissue, however, grows at a known incremental rate and does not remodel once formed. In the case of tooth enamel, the layers of incremental growth visible in deciduous and permanent crowns retain the chemical signatures of individuals' earliest years (from approximately four months in utero to 18+ years of age). When the special challenges and opportunities linked to each tissue type are accounted for, trace element analyses may then be used to comment on shifts in diet relative to changes in geographic location, socioeconomic status, or weaning.

Instruments used to analyze the trace element content of bones and dental tissues may include atomic absorption spectroscopy (AAS), atomic emission spectroscopy (AES), proton-induced X-ray emission (PIXE), neutron activation analysis (NAA), or synchrotron X-ray fluorescence (sXRF), among others. The traditional, and still most commonly employed, means of attaining trace element values involves crushing and then dissolving pieces of bone or tooth, with the resulting solution being analyzed via inductively

coupled plasma mass spectroscopy (ICP-MS). In recent years, the sensitivity of ICP-MS measurements has been combined with the precise sampling capabilities of laser ablation systems (LA-ICP-MS). These systems allow for the microsampling of bone and tooth tissues, with material removed via laser from areas as small as 20 or 5 microns producing good quality data. LA-ICP-MS and other minimally destructive techniques allow for the exploration of elemental variation within tissues (and their specific times of formation).

Future directions

Going forward, trace element analyses of human remains will likely continue to explore microspatial analyses that help to avoid complete destruction of irreplaceable samples. When combined with histological information regarding internal microstructures of tissues, these microspatial sampling strategies will continue to reveal more about the complexities of trace element incorporation, and the various factors acting upon it. Further exploration of non-traditional paleodietary indicators, such as Br (Dolphin et al. 2013), or of elemental indicators of population movements (e.g., neodymium), may expand the kinds of trace elements that researchers draw upon. The growth of interest in trace elements other than Sr, Ba, and Zn, and the combination of trace element and stable isotope analyses by several researchers, suggests that multiple means of assessing aspects of diet could produce more nuanced understandings of paleodiets in the years to come. While there will undoubtedly be further improvements of instrumentation and sampling strategies, the most important barrier that researchers will need to work to overcome is the incomplete understanding of what most trace elements actually reveal about diet, if anything. Future interpretations will need to consider inter-elemental interactions, the impact of dietary quality and micronutrient bioavailability, and the effects of reproductive status, growth, and development, and health status on variability in values. Paleodietary modeling based upon data collected from well-documented contemporary tooth

biobanks may also shed light on the complexities of using trace elements to infer past diets. Biobanking projects such as the Norwegian Mother and Child Cohort Study (MoBa) and the Avon Longitudinal Study of Parents and Children (ALSPAC), with their samples of tens of thousands of teeth, and years of longitudinal data regarding diets, activity, and health are providing insights on contemporary epidemiology, but can also be used to gain new perspectives on the appropriate engagement of trace elements when reconstructing aspects of past lives.

Differential Diagnosis

DELLA COLLINS COOK

Indiana University, USA

Differential diagnosis is a procedure for deciding what problem a patient has through systematic comparison of diseases with overlapping signs and symptoms. The concept developed in parallel with formal diagnosis in systematics. The *Oxford English Dictionary* credits the first use in English to the 1829 translation of a French dermatology text. Modern physicians can download cell phone apps that write a differential diagnosis to fit the case at hand, and there are versions that use probabilistic models. This standard practice in medicine has been adapted by paleopathologists for use in ancient remains.

The American physician Joseph Jones (1833–96) is credited with introducing differential diagnosis to paleopathology in his 1876 Smithsonian monograph *Explorations of the Aboriginal Remains of Tennessee*. Although Jones did not use the phrase as such, his diagnosis of ancient syphilis is detailed and technologically advanced for its day. Like Jones, many of the early contributors to paleopathology were physicians who engaged in informal differential diagnosis as a matter of course. Formal presentation of the technique of differential diagnosis was slow to appear in anthropology and archaeology journals. The first appearance of the phrase in *American Antiquity* is in 1945, in an article on the misdiagnosis of congenital anomalies such as trepanation, by geneticist William M. Goldsmith. In the first use in the *American Journal of Physical Anthropology*, in 1952, archaeologist William A. Ritchie identifies tuberculosis in the New World, citing a 1946 case study by Venezuelan physician Antonio Requena that presented a differential diagnosis. Ritchie himself consulted a panel of physicians. The earliest use in *Antiquity* is in 1988: Nicholas Reynolds takes to task a sensational overinterpretation of Anglo-Saxon mortuary practices, suggesting

that differential diagnosis of rape is problematic. Surprisingly, none of these authors presents a formal differential diagnosis, and all reflect the participation of physicians in identifying diseases.

All paleopathologists do differential diagnosis, whether or not they include a formal presentation of the procedure in their written reports. Publishing one's differential diagnosis is a stylistic and rhetorical choice in science writing. Some researchers take an extremely positive approach to identifying diseases and speak or write from authority. Others prefer to show their work, addressing inferences, probabilities, and ambiguities. This choice is particularly appropriate when a study concerns subjects far removed in time and way of life. There is lively debate, particularly about diseases in fossil humans. For example, Nariokotome, the 1.5-million-year-old *Homo erectus* adolescent from Kenya, was once thought to have *scoliosis*—lateral curvature of the spine—*spondyloepiphyseal dysplasia tarda*—a dwarfism syndrome—and *spina bifida occulta*—a developmental defect of the sacrum. Careful attention to features characteristic of each of these conditions, together with a detailed differential diagnosis of syndromes affecting the spine in modern humans, shows that the supposedly pathological features identified in the earlier studies are either normal in fossil humans or normal in immature spines (Scheiss and Haeusler 2013). The Nariokotome Boy was in good health when he died, and was not abnormally short.

Disease in domestic animals is a relatively new topic that offers insight into ancient attitudes and behaviors. A multidisciplinary team including a veterinarian examined a dog burial from medieval Guimps in France. In addition to several healed and healing fractures, the dog had a curved radius caused by injury to the developing forearm and a dislocated kneecap, both subjected to differential diagnosis. Appealing to “diagnostic parsimony,” the authors attribute all the injuries to abuse (Binois et al. 2013, 44), pointing out that there has been little attention to multiple trauma in the paleopathology of animals.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0188

The technical difficulties of differential diagnosis deserve attention when similar diseases have overlapping signs (Blau 2005), or affect the skeleton only secondarily (Lefort and Bennike 2007). One example is a child from a kurgan in Uzbekistan with an opening in the skull at *bregma*, the intersection of the coronal and sagittal sutures. Postmortem damage, trauma, surgery, infection, and several developmental defects are explored in the differential diagnosis. A second example is a man from the Æbelholt Monastery in Denmark, a medieval leprosarium. Leprosy, treponematosi, smallpox, ergotism, rheumatoid arthritis, and sarcoidosis are included as differential diagnosis that identifies leprosy as the most probable cause of this man's bone lesions (Lefort and Bennike 2007). His medieval contemporaries were right in their diagnosis.

A problem particular to paleopathology is diseases for which conventional diagnosis depends heavily on medical history, soft tissue histology, or serology not available from ancient remains. The sacrum of an Egyptian woman from the twenty-sixth dynasty shows an unusual pattern of new bone growth and destructive lesions. A differential diagnosis including five kinds of tumors, three kinds of cysts, and several infectious diseases is sorted out using histology (Strouhal and Němečková 2004). The studies cited here appear in journals that include many excellent differential diagnoses.

The best differential diagnoses are built on a careful reading of the medical literature and organized to make the most of the limited features that can be observed in a skeleton or mummy. Formal, tabular presentation clarifies the author's logic. Systematic texts written by and for paleopathologists on joint diseases, metabolic diseases, ancient medicine, and the like aid in economical presentation of differential diagnosis. Careful studies of known-diagnosis collections and clinical records are particularly important in critical evaluation of differential diagnosis as applied to ancient remains (Santos and Roberts 2006).

Differential diagnosis depends on careful fieldwork, recovery, and curation. Archaeologists should screen around extremities and body cavities, recording in detail the location of any unusual items. Training for excavators of

human remains should include some awareness of gallstones, bladder stones, gastrointestinal tract contents, and calcified tissues relevant to ancient health. Differentiating amputation from poor recovery or death during childbirth from funeral practices can depend on good field documentation. Details of limb positions may be important in some diagnoses. Teamwork is essential, because the rapid growth of radiological, histological, and biochemical techniques that permit the differentiation of similar diseases requires interdisciplinary effort.

Some paleopathologists have stretched the phrase differential diagnosis to fit the identification of ancient diseases at a population level. If the features characteristic of a disease are present in a series of remains from a site or region—or for some researchers if they covary—that disease must have been present. Whether a given person had the disease is seen as a less-important question. This is a misuse of the medical concept, which applies to individual patients. Its use distances the language of paleopathology from that of clinical medicine in eccentric and unnecessary ways, when neologisms such as *paleoepidemiology* or *population pattern* are more accurate and less liable to misunderstanding across disciplinary lines.

Three limitations of differential diagnosis should be kept in mind. First, the late Donald Ortner of the Smithsonian Institution frequently reminded paleopathologists of the old saw “a dog may have both ticks and fleas.” The features of a given skeleton or mummy may be the result of two or more disease processes, whereas differential diagnosis attempts to fit them into a single entity. Second, many medical texts remind us that “when you hear hoof beats, you shouldn't think of zebras.” It is tempting to favor a rare condition not yet identified among ancient people when a more common condition is more likely. Third, differential diagnosis is possible only for diseases that conform to a modern clinical picture. Infectious diseases may have evolved in ways that change their features over time. Environmental conditions and life-history constraints may alter the frequency and covariation of features of ancient disease. These complications are perhaps the most interesting questions in paleopathology.

Discrete Traits

VICTORIA S. SPRINGER

Troy University, USA

Discrete traits are those characteristics of a skeleton and dentition that can vary individually or by sex, kinship, population, or species. Also called discontinuous, morphological, or non-metric traits, they are measured on a categorical or ordinal scale. These traits are heritable and believed to be selectively neutral (conferring no evolutionary advantage). As such, they are useful in estimating ancestry, kinship, biological distance (see BIOLOGICAL DISTANCE), or sex (see ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY) in bioarchaeology (see BIOARCHAEOLOGY), forensics, or paleoanthropology. While advances are being made in the use of ancient DNA to answer many of these questions, discrete traits are often a better option due to taphonomic constraints (see DNA: MITOCHONDRIAL). Most bioarchaeological discrete trait research emphasizes dental traits because teeth are well preserved in almost all archaeological contexts, while other skeletal elements and DNA will degrade more quickly over time. Discrete skeletal traits provide an advantage over metric traits because they can be scored without having complete skeletal elements.

Discrete dental traits are typically shape variations. The majority of traits are specific extra cusps or ridges, like the metaconule, a fifth cusp on the maxillary molars that can be present between the distal two cusps. Dental traits can also include position or gross morphology, such as incisors that do not sit flush in the dental row or a dramatic size reduction up to congenital absence. Cranial and skeletal nonmetric traits include variations in the growth process of bone leading to variations in foramina or additional bone features. Cranial discrete traits are often additional foramina or suture variations, such as the presence of a notch or foramen above the eye orbit or a

short suture under the orbit. Postcranial discrete traits are more varied, but often involve additional foramina or variations in the shape of articulations.

Throughout the nineteenth and early twentieth centuries, anthropologists described individual dental variation by especially focusing on single traits in single populations, like the additional Carabelli's cusp on upper molars common in modern Europeans or the taurodont molar roots of Neandertals. These single features were often used to characterize a population, although the traits are found in varying frequencies across human populations. In the early twentieth century, Aleš Hrdlička found the standardization of descriptions lacking and undertook a study of shovel-shaped incisors, of which he gave a thorough description of multiple grades of the trait when present and a comparison of the relative frequency of the trait in human populations and nonhuman primates and other mammals (Hrdlička 1920). This work began the systematic study of dental morphology and provided evidence for the biological relationships among human populations and between humans and other mammals. In the mid-twentieth century, Albert Dahlberg furthered this standardization by developing and sharing dental plaques (casts) showing three-dimensional ranked expression of several traits (Turner, Nichol, and Scott 1991). Christy Turner and colleagues updated and expanded Dahlberg's work in the Arizona State University Dental Anthropology System (ASUDAS) with further descriptions and standardized trait plaques (Turner et al. 1991; Scott and Turner 1997). With the written descriptions for recording the categorical or ordinal rank for each trait and the corresponding three-dimensional plaques, inter- and intra-observer error can be reduced within and across studies. Bailey (2002) found the modern human basis of the ASUDAS dental traits inadequate for paleoanthropological studies and described an additional 16 traits found in high frequencies in Neandertals. Despite these additions, the ASUDAS remains the standard for assessing discrete dental traits.

Similar to discrete dental traits, anthropologists identified discrete traits throughout the rest of the skeleton and cranium as early as the eighteenth century. Some features, such as an open metopic suture, which normally closes in the first few years of life, or ossicles, small accessory bones found within the sutures of the skull, were often included in early studies of skeletal collections. However, recording practices varied substantially, ranging from a minimal categorical presence/absence to an ordinal ranking of suture closure or precise identification of the number and location of ossicles. Other studies focused only on traits present in the specific population being examined. At a seminar at the Field Museum of Natural History in Chicago in 1991, multiple experts devised standard recording practices for human skeletal remains, including nonmetric traits, leading to the publication of *Standards for Data Collection from Human Skeletal Remains* (Buikstra and Ubelaker 1994). Like the ASUDAS, this guide provides descriptions of categorical or ordinal recording procedures for improved inter- and intra-observer consistency.

In the scoring of all discrete traits, standards such as the ASUDAS and *Standards for Data Collection from Human Skeletal Remains* should be followed (Buikstra and Ubelaker 1994; Turner et al. 1991). In general, scores for all traits should be recorded, including the score of absent or unobservable. Traits should be recorded from both sides of the body, although statistical analysis may only use one side. Tests of intra-observer error should be conducted on the data to ensure repeatability of results, along with inter-observer error tests if multiple people collect the data (Buikstra and Ubelaker 1994). For ease of statistical analysis, ordinal discrete trait data are often dichotomized to a present/absent observation. This process is justified by the presumed additive genetic control of dental and other skeletal traits, and standard breakpoints for dental traits are given in the ASUDAS descriptions (Turner et al. 1991). However, this process reduces variation within and among populations, limiting the usefulness of these traits for study (Buikstra and Ubelaker 1994).

The morphological traits described by the ASUDAS and *Standards* manual are heritable and believed to be selectively neutral (conferring

no evolutionary advantage), making them useful for forensics, bioarchaeology, and paleoanthropology (Buikstra and Ubelaker 1994). Some of the early descriptions of discrete traits included family studies, but more in-depth research on heritability began in the 1950s. Working with mice, Grüneberg (1951) noticed that some discrete dental traits were more common in some lineages, and cross-bred mice to determine the genetic basis for those traits. Torgersen (1951) found a similar phenomenon in cranial sutures and ossicles while studying human radiographs. Since then, multiple studies have examined human morphological traits, comparing twins, non-twin siblings, and other family members. While the actual heritability estimates vary, there is a general consensus for high heritability controlling discrete traits throughout the skeleton and dentition (Buikstra and Ubelaker 1994; Scott and Turner 1997).

Forensic anthropologists are often called to identify individuals based on skeletal remains, with both sex and ancestry often requested, although there are serious limitations in providing this information. Sex variations are dependent on the population, and “races” are socially constructed categories that are not distinguished by consistent biological divisions between those categories. For example, the practice of hypodescent (assignment of race to match the parent with the lowest social status) prevalent in the United States allows a wide variation in the ancestry of those labeled African-American, while ancestry signaling Hispanic ethnicity can vary depending on the geographic location within the United States (Edgar and Ousley 2013). However, being hereditary, discrete traits can provide useful information as long as these factors are considered. Discrete traits in the pelvis, such as the presence of a ventral arc in females, can be useful in determining sex. Using multiple discrete dental traits together in analysis can lead to fairly confident assessment of ancestry when using a representative comparative sample (Edgar and Ousley 2013). This work builds on other cranial discrete traits identified as distinctive among those with African, European, or Asian ancestry, such as the shape of the nasal bones and nasal aperture.

Determining kinship or biological distance in bioarchaeology is also aided by the use of discrete traits. This type of study increased dramatically after several studies in the 1950s showed the high heritability of these discrete traits (Buikstra and Ubelaker 1994). Biological distance studies can range from single burials or cemeteries to large interregional comparisons. At the single burial or cemetery level, discrete traits can be compared to assess the likelihood that individuals are similar enough to be considered biologically related. This can be done using rare traits or a larger number of less-unique traits. If the individuals share multiple rare traits or if other traits are found correlated at a higher frequency as compared to similar populations, the individuals are likely to be related. This was found to be the case in the Upper Paleolithic triple burial at Dolní Věstonice in the Czech Republic where the three individuals shared multiple dental traits, as well as three traits uncommon in other Paleolithic populations (Alt et al. 1997). This kind of comparison can be expanded to examining potential kinship within a cemetery or site. Finding more variation between cemeteries than within them would indicate biological relatedness factoring into burial location. Cluster analysis can be used to determine if morphological traits correlate with geographic patterning in burials, indicating kin groups buried in specific cemeteries. Again, the analysis could be expanded further to compare multiple sites, considering migrations of people if the region does not follow an isolation-by-distance model where populations become less alike the further away they are geographically. Generally, this type of study will use a distance statistic, such as a mean measure of divergence, to test the biological distance based on nonmetric traits.

Nonmetric traits can also help identify hybridization between species or admixture between distinct populations of the same species. Trait frequencies of a descendant population will often be intermediate to the two parental populations, but can also be closer to one parent or the other. Additionally, normally isolated traits will often be passed on together, a process known as linkage disequilibrium. This can lead to increased variation in the descendant population, as found in modern Pima Native Americans, who have some European admixture. Finally, rare

or abnormal traits are more common in hybrid admixed populations, such as supernumerary teeth in many nonhuman animals (Springer 2013).

DNA: Mitochondrial

JENNIFER RAFF

University of Kansas, USA

Characteristics of mitochondrial DNA

Mitochondrial DNA makes up the genome of mitochondria, the organelles in eukaryotic organisms which carry out oxidative phosphorylation, the chemical reactions by which energy is synthesized. Mitochondria are thought to be derived from an endosymbiotic prokaryote—a bacterium that may have been engulfed by another during a process known as phagocytosis, to their mutual benefit—perhaps around 2 billion years ago. Many of the genes originally located in the endosymbiont's genome were subsequently transferred to the nuclear genome (Friedman and Nunnari 2014).

Mitochondrial DNA is unusual in several respects compared to nuclear DNA. Introns (noncoding DNA) are absent, and some codons deviate from universal genetic code. The mitochondrial genome is circular and (like bacterial genomes) consists of a “heavy” (H) strand and a “light” (L) strand, where the difference in mass is due to differing proportions of (larger) purines versus (smaller) pyrimidines in their sequences (Taanman 1999). In humans, the numbering of the positions of the mitochondrial genome's 16,569 nucleotides is done with respect to a reference sequence, known as the revised Cambridge Reference Sequence (rCRS), which was the first mitochondrial genome sequence ever published in 1981 and corrected for errors in 1999 (Andrews et al. 1999). All mitochondrial lineages are identified and classified on the basis of DNA sequence differences with respect to the rCRS. Increasingly, however, a “Reconstructed Sapiens Reference Sequence,” which takes into account archaic hominin mitochondrial genomes to reconstruct an ancestral root haplogroup for humans, is being viewed as a more phylogenetically useful

reference sequence than the rCRS, which is a European lineage.

The human mitochondrial genome has some regions whose DNA is used for the production of proteins (coding regions) and some regions that are not used for protein production (non-coding regions). The noncoding portion of the mitochondrial genome that makes up nucleotide positions 16024–576 is referred to as the control region. In addition to containing the site of the origin of DNA replication (in a region known as the D-loop, or displacement loop), the control region contains two hypervariable regions (known as HVRI and HVRII: “hypervariable region I and II”) in which DNA bases mutate at more rapid rate (roughly 10-fold in humans) than the rest of the genome.

The rest of the human mitochondrial genome (np 577–16023) contains 37 genes: 28 on the heavy (H) strand and 9 on the light (L) strand. Mitochondrial genes, which do not recombine with the nuclear genome, encode proteins and RNAs involved in energy metabolism. Mutations within mitochondrial genes have been linked to a number of disorders, including energy production, neurodegenerative diseases, and cancer (Taanman 1999).

Inheritance

The mitochondrial genome of an individual is maternally inherited. Although sperm have been observed to donate mitochondria to oocytes during fertilization, they do not appear to be inherited by later generations of cells in the embryo except in extremely rare cases. The mechanism for this phenomenon, whether through active elimination or dilution of sperm-derived mitochondria, is currently unknown. This maternal inheritance, coupled with the greater abundance of mitochondrial genomes relative to nuclear genomes in each cell, the rapid rate of mutation within the hypervariable regions, and the nonrecombining nature of the genome, make mitochondrial DNA a

record of maternal genetic history. However, due to their circular structure, all the regions of a mitochondrial genome are tightly linked and inherited together. Thus, mitochondrial genomes effectively constitute only a single genetic locus or marker. They therefore reflect the evolution and migration of a small subset of the population and are much more affected by genetic drift. Thus, there are some limitations to the inferences that can be drawn from mitochondrial-based studies alone. However, due in part to its greater abundance in cells, mitochondrial DNA is much more likely to be recoverable than nuclear DNA from ancient remains. This greater likelihood of recovery, as well as relatively less computational complexity and expense, is reflected in the greater proportion of paleogenetics literature reporting mitochondrial diversity than nuclear diversity.

Identifying ancestry

In humans, mitochondrial lineages (haplotypes) related by recent shared ancestry are classified into taxa known as haplogroups. Haplogroups are named according to a system that reflects the order of their characterization, beginning in the 1990s. Haplogroups A, B, C, D, present in indigenous American and Asian populations, were the first to be identified. Haplogroups H, I, J, and K were characterized in European populations, and haplogroup L in African populations. The early mitochondrial DNA studies were low-resolution and based on analyses of the length of fragments resulting from digestion of the genome with restriction enzymes (restriction fragment length polymorphisms, or RFLPs). Refinement of phylogenetic relationships between haplogroups steadily improved as direct sequencing, first of HVR I and II and then of the noncoding portions of the genome, became increasingly common. As resolution and sampling coverage of populations increased, new genetic variation was uncovered and additional haplogroups and sub-haplogroups were added to the mitochondrial phylogenetic tree. Today the most up-to-date mtDNA tree (phyloree.org), is based on over 25,000 complete mitochondrial genomes, the highest level of resolution possible. It currently contains over 5,400 haplogroups and is revised regularly to

include new mitochondrial genetic diversity as it is identified. (van Oven and Kayser 2008)

Because the distribution of mitochondrial lineages largely reflects the genetic histories of populations, mitochondrial DNA-based studies in both ancient and contemporary populations have been used to identify significant evolutionary events in human history. For example, ancient mitochondrial DNA recovered from skeletal elements in the Denisova Cave in the Altai mountains of Siberia has revealed the existence of a previously unknown hominin species around 30,000–50,000 YBP, genetically distinct from both Neandertals and *H. sapiens* (Krause et al. 2010). Studies of mitochondrial DNA from contemporary populations in sub-Saharan Africa strongly supported a model of human origins in Africa: contemporary sub-Saharan African populations were found to have approximately twice the amount of mitochondrial sequence diversity as non-African populations, as would be predicted for a region with the longest history of human occupation (Kivisild 2015).

Mitochondrial DNA studies, both ancient and modern, have been used in conjunction with archaeological evidence to track the migration history of *H. sapiens* out of Africa and across the world. By correlating estimates of sequence mutation rates to the number of mutations in different lineages since they diverged, the coalescence times of haplogroups to their most recent common ancestor (TMRCA) can be calculated, allowing migrations to be put into a temporal context. For example, the TMRCA for sub-Saharan African lineages (L0–L6) has been estimated to be 171,500 $\pm$ 50,000 years before present (YBP), which is roughly congruent with archaeological and fossil evidence for the emergence of anatomically modern *H. sapiens* (AMHS). All non-African haplogroups can be classified into just two macro-haplogroups, M and N, which last shared a common ancestor with African clades between 62–95,000 years before present. The Americas were the last continents to be peopled, via one or more movements out of Beringia, which was a continental connection between North America and Asia during the Last Glacial Maximum (~28,000 and 18,000 cal BP). The observation that pre-European contact indigenous American populations harbored the least mitochondrial genetic diversity compared

to other populations worldwide is consistent with the model that the Americas were the last continents to be peopled (approximately 15,000 years YBP). (Behar et al. 2008; Kivisild 2015)

Mitochondrial genetic diversity can be used to identify significant demographic events in past populations, including temporal changes in effective population size (N_e) (the number of individuals who contribute offspring to the next generation) and genetic bottlenecks, gene flow, or population expansions. For example, a recent study of Neandertal mitochondrial genomes supported a hypothesis that their Denisovan-like maternal lineages were largely replaced by gene flow from African hominins with mitochondrial lineages more closely related to AMHS, sometime prior to 270,000 years before present. (Posth et al. 2017)

DNA: Next Generation Sequencing

ANNA E. LINDERHOLM

Texas A&M University, USA

Since the discovery of the DNA double helix in 1953, a lot of progress has been made in order to read, or sequence, the DNA. The first method, now known as Sanger sequencing (Sanger, Nicklen, and Coulson 1977), utilized chain-termination. This process involves a single-stranded DNA molecule, a primer (a starting block, usually a 15–20 base pair synthetic DNA molecule) and deoxynucleotidetriphosphates (dNTPs), that is, the bases (A, C, T, and G) that will build a new string of DNA; when a modified dNTP is added, the chain breaks and a signal is sent off and that is when the sequence is read. This technique mirrors the polymerase chain reaction (PCR), where the same reagents are used (primer, dNTPs) plus a controlling/working enzyme (Taq polymerase), this time to copy the single DNA strands rather than sequencing them. By copying each molecule, within a few cycles millions of identical DNA molecules have been produced.

This platform has been updated and automated since the 1970s, and can now analyze 384 samples in a single batch with 24 runs per day. However, the newer, next generation sequencing (NGS, also called high throughput sequencing) has revolutionized DNA sequencing in general, and has caused explosive growth in the research field of ancient DNA (aDNA) (Krause and Pääbo 2016). There are two main reasons for this. First, only very short segments of DNA (35–150 base pairs, bp) can be obtained from archaeological samples. The aDNA has already been fragmented by chemistry and time; this fragmentation starts to happen directly upon an organism's death. Second, instead of relying on traditional Sanger sequencing to obtain one sequence per sample, by using NGS platforms one obtains many thousands of sequences per sample. A single run can now

produce up to a million reads (Linderholm 2016). So even though the aDNA is heavily degraded into short fragments (40–50 bp), with thousands of sequences obtained from a single sample, alignments can be made and longer stretches of DNA can be assembled and read, thus taking the aDNA field from genetics into genomics.

There are two technical concepts responsible for this huge achievement of obtaining millions of reads from one sample/run: sequencing by ligation (SBL) and sequencing by synthesis (SBS). Different commercial companies have used variations of these to release their own proprietary platforms (Goodwin, McPherson, and McCombie 2016).

Roche was the first company to develop and release a NGS platform, when they introduced the so-called 454 platform back in 2005. The platform utilizes pyrosequencing as the basic technology, rather than traditional Sanger sequencing. This new system was capable of sequencing roughly 400–600 megabases of DNA per 10-hour run. One year after the release of the 454 machine, a paper was published in *Nature* investigating Neanderthal remains using the 454 for the first time on archaeological material, launching the use of NGS in the field of aDNA (Green et al. 2006). The 454 platform used emulsion PCR as the template amplification strategy, and this technique paved the way for several other platforms/machines such as the Ion Torrent. The emulsion PCR is a system in which micelle droplets (similar to oil drops in water) are loaded with primer, DNA template, dNTPs and Taq polymerase, creating millions of independent PCR machines. The amplification itself happens when the template hybridizes to bead-bound primers; once the amplification has taken place the complement strand disassociates, leaving bead-bound single-stranded DNA (ssDNA) templates. These templates can then be sequenced, adding one base at a time, utilizing the light emitted as a signal of base incorporation (a form of SBS). The 454 was discontinued in 2013 and technical support of the platform will end in 2016. Although the 454 platform has been discontinued, some laboratories

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0195

are still using the machine, and more papers will likely be published using results obtained from this platform.

Not long after the 454 platform was introduced, Solexa released a new form of NGS platform, the Genome Analyzer (GA). Illumina subsequently acquired Solexa, and rapidly released a string of commercially available NGS machines, MiSeq and HiSeq being the two most utilized machines in laboratories across the world. They have been the dominant platforms used in any genetic field, but are particularly preferred for aDNA research (Goodwin et al. 2016). The Illumina platform uses a solid glass surface (a flowcell with 1, 2, or 8 lanes) covered with a coating of surface-bound primers (p5 and p7) that are complementary to the library adaptors (a mirror piece of the primer DNA sequence). These will capture individual molecules and, via “bridge PCR” (an amplification step), create a cluster. The bridge PCR works as follows: the surface is washed with a mixture of dNTPs and polymerase. Priming occurs as the free end of the captured fragment bends or “bridges” to a complementary oligo on the surface. Repeated cycles of this step results in localized amplification of individual DNA fragments across the surface of the flowcell. On one flowcell there can be up to 200 million individual clusters, each with 1,000 copies of each original fragment. Once the clusters have been created, sequencing takes place, using the reversible terminator-based method. Here each single base (all terminator-bound dNTPs) is incorporated, the fluorescent dye (one for each base) is identified by laser excitation (using four different color emissions to determine the base that has been incorporated), and an image is created. The dye is then cleaved to allow the next round of nucleotide incorporation. Base calls are then made from these images (another example of SBS) (Mardis 2008).

ThermoFisher is the only company that has based the template amplification strategy on sequencing by ligation (SBL), with the NGS SOLiD wildfire; it uses a solid-phase template walking system. This sequence extension method uses DNA ligase rather than polymerase in conjunction with one- or two-base-encoded probes to read the DNA molecule.

One of the biggest developments for the NGS platforms has been paired-end (PE) sequencing.

This allows the DNA molecule to be read in both directions (forward and reverse), giving the investigator twice as much information from each extracted fragment for the same cost and time. Prior to this development, only one of the DNA strands was read.

The process of obtaining a sequence or whole genome (i.e., the entire genetic material from an organism) is as follows (i.e., from sample to sequence):

1. *Extraction:* The first step is to extract the DNA from the sample (bone, teeth, hair, tissue, soil, or water). There are several methods for this, depending on the platforms to be used or on the sample material (Rohland and Hofreiter 2007).
2. *Library build:* Regardless of platform, the next step after the DNA has been extracted is to build a “library” (Head et al. 2014). Since aDNA is already fragmented what is left to do is to index the samples. This is especially true if you plan to run multiple samples on one lane, that is, pooling samples. For double-stranded libraries, building is an easy three-step process (using a commercial kit). If the sample is less well preserved, older, or unique, a single-stranded library can be built following the same principles, but the lab procedure is slightly more complicated and more expensive.
3. *Quantification:* NGS is a technique that depends on adding a precise amount of fragmented DNA onto a solid surface. This means that it is imperative that the DNA is quantified as accurately as possible. Currently there is no gold standard for this. Once the library has been built it needs to be checked for quality and quantity. To check the quality, a Bioanalyser or a TapeStation (Agilent) can be used. To check the quantity, two routes are possible, fluorometry (Qubit, ThermoFisher Scientific) or real-time PCR (qPCR). Libraries can either be pooled, based upon the results from the previous step (to give equimolar amounts of each library to make the run unbiased), or put straight to be sequenced.

4. *Cluster generation and sequencing:* The samples are then run on one of the available platforms; the choice depends on the question, time and/or money.
5. *Data analysis:* Once the NGS data have been obtained, they undergo several steps before they can be used. Quality control is the most important one; initially the sequence processed is scored and the sequences are given as FastQ files. These files will include both the DNA sequence and the quality score for each base in the sequence. This score measures the confidence of it being called/read correctly by the sequencer.
6. *Pipelines:* To analyze the FastQ files, a whole range of bioinformatic software tools are available. Most aDNA laboratories have a proprietary pipeline. The pipelines include multiple steps: (a) removal of any residual adaptor sequences; (b) removal of poor-quality sequences; (c) checking for authentic DNA sequences; (d) removal of any tiling (i.e., a multitude of the same sequence); (e) assembly of the authenticated sequences; and (f) blasting (comparing) of the sequences against a known reference sequence or against the online database GenBank. Once these steps have taken place, the coverage (that is, the average number each base has been sequenced/covered) can be determined.
7. *Data presentation:* By using any number of programs such as TREEMIX, Plink, MEGAN, or GeneWiz, graphs and phylogenetic trees can be created to visualize the data obtained.

Because of the multitude of short reads generated from aDNA, the computational resources needed to analyze and store these datasets is considerable. One run can equal 1 Tb of data. The use of computational clusters has risen in the last five years as a consequence.

As each run produces more and more data, even outpacing Moore's law, the price per run has dropped significantly. Today it is possible to sequence a whole human genome for under \$1000; when the first human genome was sequenced it cost more than 3 billion dollars. This

price drop and increase in data has made this technology much more available.

Embodiment

MARÍA CECILIA LOZADA

The University of Chicago, USA

researchers have also evaluated the relationship between object/subject, boundaries between animate/inanimate, locus of personhood (e.g., the head in many societies), and additional cultural categories when reconstructing the past.

Embodiment in archaeological discourse

The term “embodiment” first appeared in the vast and multifaceted research regarding “the body” during the 1970s. Since this term is rather fluid, definitions and studies of it are rather extensive. However, Turner (2003, xvii) offers a useful explanation of the term that is applicable to archaeological studies that deal with the reconstruction of past societies through the study of material culture. For Turner, embodiment represents an attempt to understand human practices that are organized around the life course of an individual, including different life stages such as birth, maturation, reproduction, and death.

One of the best archaeological assessments of embodiment comes from Meskell and Joyce (2003) in their book *Embodied Lives: Figuring Ancient Maya and Egyptian Experience*. In their study, Meskell and Joyce (2003) examine the interrelatedness of representations (visual, written, and material) of bodily practices that include body modification, adornment, clothing, cosmetics, and human–animal relations. Their goal was to explore the essential notions of the body and reconstruct the living experiences of human beings and their underlying principles. In this respect, Meskell and Joyce (2003, 17) transcend the Cartesian dichotomy of mind and body interpretation, thus opening the possibility of framing embodiment as a concept distinct from notions of duality, hierarchy, and rational privilege. Other archaeologists have since questioned contemporary assumptions of binary sex structure systems (male/female), sex and gender dichotomies (when assigned biological sex and gender perceptions do not align), and locus of gender (features in the body that represent maleness, femaleness, or other gender(s)). Beyond these sex and gender reconsiderations,

Embodiment in bioarchaeological studies

While material culture has been extremely useful in examining certain aspects of embodiment in ancient societies, it is limited because it does not reflect all facets of an individual's lived experience. Viewed from a different perspective, Nancy Krieger (2001), a social epidemiologist, defines embodiment as a term that refers to how people literally incorporate, biologically, the material and social world in which they live, beginning in utero and continuing until death. In this context, the study of embodiment from the medical/social perspective is relevant today, as embodiment can be seen as a lens through which to study inequality or disparities such as (1) differences in living conditions that have a direct effect on the body, and (2) how the body can indicate social stress (suffering) or stigmatization that a group experiences.

From a bioarchaeological perspective, the body can be conceptualized as a malleable canvas that imprints both conscious and subconscious processes. Researchers have explored the biological imprints of lived experiences from human remains, such as embodiment in the past. In fact, the publication of *The Body as Material Culture: A Theoretical Osteoarchaeology* by Joanna R. Sofaer (2006) theoretically positions the physical body at the forefront of theories of embodiment by considering the body as a form of material culture inextricably linked to particular social and historical processes. While this book is one of the most cited works when discussing embodiment from the bioarchaeological perspective, other scholars such as Buikstra and Scott (2006) indicate that researchers need to be careful with such an approach. In their view, Sofaer (2006) does not consider all the factors

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0213

that may impact the body, including cultural and historical dimensions, genetics, and other biological processes. Buikstra and Scott (2006) suggest that both the biological and social body must be interpreted together through a highly contextualized study of mortuary contexts.

Although the term “embodiment” permeates the recent bioarchaeological literature, some studies have been more successful at linking theoretical models and empirical data. A few examples of this work offer an integrated approach to specific questions regarding embodiment in the past.

Sex and gender

In a short yet relevant report, Walker and Cook (1998) alerted readers of the *American Journal of Physical Anthropology* to the distinctions between the terms sex and gender, as quite often both terms have been used as synonyms. In brief, according to these authors, sex refers to the biological differences between male and female, while gender refers to the socially constructed roles that individuals may have in society. Bioarchaeologists typically assess sex based on a series of morphological traits, while gender is interpreted through an archaeological lens that includes clothing, hairstyles, grave goods, imagery, and historical descriptions. However, some researchers have raised concerns, stating that sex cannot be based solely on bone morphology, and furthermore the interpretation of the gendered body and gender roles through the study of mortuary contexts may be limited as the funerary ritual is most likely created by mourners.

These researchers argue that a better understanding of gender in the past can be seen through the study of human remains, as socially constructed gender categories through performative actions and/or habitual activities are embodied in the biological body. For example, the study of auditory exostosis has been used for this purpose. An auditory exostosis is an abnormal bone growth within the external auditory meatus of the temporal bone that develops as the result of sustained and frequent participation in aquatic activities. Based on this theory of causation, researchers have been able to identify gender roles in the past. Standen, Arriaza, and Santoro (1997) detected a relatively high prevalence of

auditory exostoses among adult males in past Chilean populations that lived along the Pacific Coast. Males were more likely to be engaged in sustained aquatic activities (e.g., fishing) based on gender roles, and this social practice became embodied in their bones through formation of auditory exostoses.

Other researchers have used a similar approach to challenge binary concepts of gender roles in the past, as many societies recognize more than two genders. Osteological markers such as musculoskeletal stress markers (MSM) of female-associated daily activities in male skeletons and vice versa have been interpreted as evidence of a third gender (Hollimon 2017). Other activity-associated markers that have been used to infer gender roles from human remains include degenerative joint disease (DJD), squatting facets, and dental wear patterning.

Cranial modification

Cranial modification represents the intentional reshaping of the head of an individual, beginning shortly after birth, which requires significant time and societal investment to be successful (see CRANIAL SHAPING). This practice was common in the past in the Andes and, in conjunction with ethnographic and archaeological data, researchers have used this permanent body alteration as an example of embodiment in the past. For instance, in the highlands, cranial modification embodied geographical borders among the Tiwanaku, as there were clear regional patterns of cranial types. On the other hand, head shapes embodied the lived experiences and worldview of different occupational subgroups or ethnicities, such as with the coastal Chiribaya, including those who were dependent upon a marine-based subsistence versus farmers who depended on agriculture. Both groups had their own distinctive head shape.

In Mesoamerica, head modification in past societies such as the Maya was a common practice, although researchers have outlined a different scenario. The process of molding the head prevents the wandering of the soul of infants, while also crafting them into adults. These and other topics regarding embodiment and cranial modification are addressed in the edited volume

by Tiesler and Lozada (2018) who suggest that head shape embodies deeper understandings of ontological notions of the being and of the native cosmos in ancient Mesoamerica and the Andes.

Other forms of body modification

While cranial modification was initiated when an infant was born, dental decoration among the Maya embodied life stages such as the transition from childhood to adulthood. Central incisors were shaped similar to the Mayan sign for *ik*, a term that alludes to wind or breath, and interpreted as a source of vitality during this rite of passage (Scherer 2018).

Bioarchaeologists may not have the opportunity to fully study the impact of other permanent forms of body modification from skeletal remains. However, from anthropological and historical accounts there is ample evidence for the permanent manipulation of the body that includes foot binding and neck rings, and many others. Foot binding in ancient China during the initial years of its practice embodied the lifestyle of certain upper-class women who did not need to move. Historical records suggest that they spent most of their lives in a sitting position as their bound feet hindered their ability to walk. Similar to cranial modification, and unlike other forms of body modification, foot binding was a social imposition, and once the natural anatomy of the feet was reshaped, this process could not be reversed.

The use of neck rings has been documented among the Paduang women living in Burma, and, unlike cranial modification and foot binding, this practice still exists. Legend says that the rings around the neck protected women from tiger attacks; however, researchers seem to agree that a long neck coiled with brass rings represented an elite symbol. Today, it is mostly used to attract tourists. While the meaning of these body alterations transformed over time, researchers such as Stone (2012) propose that these practices embody indirect modes of structural violence toward women in these societies.

Diseases

As certain chronic and endemic diseases leave indelible marks in the body, numerous case

studies document how people embodied their biological and social living conditions in the past. These conditions were shaped by genetic and biological factors as well as the social and physical environment. For instance, urbanization resulted in changes in living conditions (environmental and social), such as increased population density. This change in living conditions allowed for the transmission of tuberculosis in the past, to the extent that the detection of tuberculosis in human skeletal remains can be seen as one sign of increasing urbanization. Another example of disease-associated embodiment can be seen in chronic illnesses such as juvenile idiopathic arthritis (JIA), a type of arthritis that affects children and young adults. Skeletal evidence of this condition was reported by Buikstra et al. (1990) who describe a juvenile skeleton dated to 900–1050 CE in southern Peru. The extensive osseous lesions of this individual suggest that bipedal locomotion, functional use of the upper extremities, and mastication would have been difficult if not impossible, and that the onset of the disease was probably very early in life. This condition also left important clues regarding the individual's social conditions through embodiment, revealing how the community cared for and culturally viewed individuals with chronic, debilitating conditions such as JIA.

Estimating Adult Age at Death: Cranial Suture Closure

J. ALEX CANTERBURY
Texas A&M University, USA

The estimation of age at death, along with sex, is one of the primary objectives of skeletal analysis conducted by both bioarchaeologists (see BIOARCHAEOLOGY) and forensic anthropologists. Because of the importance of estimating age at death as precisely and accurately as possible, a large number of techniques and methods have been developed using various skeletal elements and features, including the skull. These methods are generally divided into those appropriate for estimating age for immature versus adult remains, with methods for immature remains tracking the growth of the individual (see ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION; ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH; and ESTIMATING SUBADULT AGE: EPIPHYSEAL UNION) and methods for adult remains tracking their progressive breakdown (see ESTIMATING ADULT AGE: AURICULAR SURFACE MORPHOLOGY; ESTIMATING ADULT AGE: PUBIC MORPHOLOGY; and ESTIMATING ADULT AGE: TRANSITION ANALYSIS). One technique to estimate the age at death of adult remains is by observation of closure of the cranial sutures—the lines of contact between individual bones of the skull.

Cranial suture closure techniques are based on assessment of an individual's degree of cranial synostosis—the fusion of adjacent bones of the skull at the sutures. Because cranial bone growth occurs at the sutures, they tend to remain open (barring precocious closure in the case of craniosynostosis) during childhood and adolescence. Following cessation of growth—generally between 18 and 25 years of age—these sutures begin to progressively fuse in a predictable pattern. With advanced age, this

process can eventually result in no, or very little, visible division between individual bones. When presented with cranial remains, skeletal biologists can assess both the degree and pattern of cranial suture closure (i.e., which sutures have fused and which remain open) to estimate age at death.

Cranial suture closure is unusual among analytical techniques frequently employed by skeletal biologists in that it has a remarkably long history of academic investigation. The fusion of cranial sutures with age was first described by the father of comparative anatomy, Andreas Vesalius, in the mid-sixteenth century and has remained a topic of inquiry and debate until the present day (see Masset 1989 for a comprehensive review). While numerous specific techniques for estimating age at death from suture closure have been proposed, most modern applications largely derive from the methods developed by Meindl and Lovejoy (1985). One-centimeter sections at 11 points on the skull are scored according to degree of closure. The sum of these scores corresponds to a mean age at death and an estimated age range for the given degree of fusion. These age ranges were derived from observation of cranial suture closure among a reference population, or a comparative sample for which age at death is known.

While scoring degree of fusion at established points on the cranium remains fairly standard, there continues to be considerable disagreement on which sutures or series of sutures provide the most accurate estimations of age at death. For example, earlier scholars argued that sutures occurring on the external surface of the cranium (ectocranial sutures) are more reliable for estimating age at death than those visible on the internal surface of the cranium (endocranial sutures), while more recently the opposite has been suggested (Meindl and Lovejoy 1985). Separate techniques based on other suites of sutures, most notably those of the palate, have also been proposed (Beauthier et al. 2010; Mann et al. 1991). Furthermore, there is considerable debate as to how demographic factors, such as ancestry and sex, can influence the rate of suture closure.

For example, Nawrocki (1998) found that the rate and pattern of suture closure differed between individuals of African versus European descent, as well as between males and females. Findings such as these have led some to argue for the development of population-specific reference samples, so that the age distribution of the reference sample approximates the age distribution of the studied population as closely as possible (Masset 1989). Other researchers argue that ancestry and sex have zero or negligible effect on cranial suture closure, and are therefore irrelevant when estimating age at death from sutures (Meindl and Lovejoy 1985).

Even when cranial suture closure aging can be performed, there remain pitfalls. All techniques for estimating age at death for adult remains result in age ranges that are incredibly wide, particularly among older individuals, a result of the extreme level of individual variation in suture closure. Also, because most cranial suture closure techniques rely on composite scoring of multiple sites on the cranium, by definition all must be preserved for age estimation to be conducted. If even one requisite location for a given technique is unobservable, then aging based on suture closure is impossible. This can be especially problematic in archaeological contexts in which skeletal remains, and particularly delicate cranial bones, tend to be highly fragmentary. However, a more recently developed aging technique, transition analysis, utilizes cranial suture closure along with other age estimators (including pubic symphysis and auricular surface) but does not require a completely preserved suite of sutures. Instead, an individual maximum likelihood age estimate is obtained for each individual and incorporates uncertainty introduced by missing data. Sutures are the least useful indicators incorporated into this method; however, partial suture data can be incorporated into age estimates based largely on other diagnostic skeletal features (Boldsen et al. 2002).

Given these considerations, it is perhaps not surprising that, from a survey of skeletal biologists, Garvin and Passalacqua (2012) found that cranial suture closure ranks among the least desirable techniques for estimating adult age at death. In fact, cranial suture closure methods are typically used only when preferable techniques, such as pubic symphysis and auricular

surface morphology, are impossible. When cranial suture techniques are utilized, it is generally only to broadly establish the individual's stage of adulthood and preferably only in conjunction with other, more reliable aging techniques. For example, Buikstra and Ubelaker (1994) recommend a hybrid approach, utilizing ectocranial, endocranial, and palatal sutures to broadly sort an individual into young (20–34 years), middle (35–49 years), or old (50+ years) adulthood.

Despite these concerns and issues, cranial suture closure remains a frequently used tool for estimating age at death for adults for the simple fact that cranial remains are among the most commonly preserved skeletal elements in both archaeological and forensic contexts that can provide information about adult age at death. This is particularly true compared to fragile features like the pubic symphysis, which are more robust for estimating age at death, but are also relatively fragile, and, therefore, frequently suffer from poor preservation. Furthermore, cranial suture closure remains one of the few methodologies available to estimate age in older adults, particularly in cases where dentition is not preserved (Meindl and Lovejoy 1985). As a result, researchers continue to devote efforts to refining techniques and expanding reference populations to continually improve the usefulness and precision of cranial suture closure techniques, particularly through the use of virtual imaging technologies such as computed tomography (CT) (see COMPUTED TOMOGRAPHY) (Chiba et al. 2013). While unfortunately little concrete progress has yet been made on these fronts, these recent developments indicate that the long history of estimating adult age from cranial suture closure is unlikely to end anytime soon.

Estimating Adult Age: Auricular Surface Morphology

JO BUCKBERRY

University of Bradford, UK

The auricular surface is located on the posterior portion of the ilium and has been used to estimate adult age at death since 1985 and is typically used in combination with other skeletal age estimators (see ESTIMATING ADULT AGE: PUBIC MORPHOLOGY and ESTIMATING ADULT AGE: TRANSITION ANALYSIS). The auricular surface is often utilized because it is robust, surviving the burial environment much more often than the fragile pubic symphysis (see ESTIMATING ADULT AGE: PUBIC MORPHOLOGY), and because age-related changes continue into the later decades of life. It is likely that the anatomy of the sacro-iliac joint influences age-related changes.

The auricular surfaces of the ilium are part of the sacroiliac joints (SIJ) between the sacrum and the left and right ossa coxae (pelvic bones). The size and shape of the auricular joint surfaces are variable between individuals and between the left and right sides of an individual. The SIJ is a complex joint which allows a small amount of movement (although the degree of movement is debated) and is stabilized by ligaments. In the final stages of pregnancy, hormones allow the ligaments to relax, allowing for greater movement of the SIJ during childbirth (Vleeming et al. 2012). Despite this, few sex-related differences in the rate of aging have been reported. The inferior portion of the joint is synovial, whereas the superior portion of the joint is more fibrous. On the sacral side, the joint surface is covered with a thick layer of hyaline cartilage, whereas on the iliac side it is covered with a thin layer of fibrocartilage in childhood which progressively changes to hyaline cartilage with maturation (Vleeming et al. 2012). Similar age-related changes are not observed on the sacral side of the joint; this is probably due

to the differences in anatomy. Fusion of the SIJ is seen in a small percentage of older individuals (usually over 50 years of age and more commonly in males) and is associated with some pathological conditions, such as ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis (DISH).

The first formal method developed to estimate age from the auricular surface was by Lovejoy and colleagues (1985) based on observations of the Libben population (archaeological) and the Todd Collection (known-age). They described typical features of auricular surfaces which were grouped into six five-year, one ten-year, and a final, open-ended age groups. These narrow age ranges do not appear to reflect the range in age variation seen for each of the auricular surface stages (Osborne, Simmons, and Nawrocki 2004) and have low levels of accuracy. Indeed, Lovejoy et al. (1985, 21, 23) originally noted that they selected some individuals for photography that fell outside their modal age group. Key features associated with the aging process of the surface itself were billows (which are transversely organized and reduce in depth to striae), microporosity and macroporosity (which appear with increasing age), grain (the joint surface becomes more coarsely granular with increasing age), and density (which refers to the increasingly solid surface appearance of the bone and which replaces coarsely granular bone). These are associated with changes to the apex (the edge of the joint adjacent to the end of the arcuate line) and the retroauricular area (located posterior to the joint surface). Changes in the latter two areas were referred to as increasing “activity” by Lovejoy and colleagues.

In 2002, Buckberry and Chamberlain (2002) published the “revised auricular surface” method, which recorded five features of the surface (transverse organization, surface texture, microporosity, macroporosity, and apical changes) independently, before combining them as a composite score to estimate age. The features utilized were based on those of Lovejoy and colleagues and were quantified by assessing either the percentage of the surface or which of the two demifaces were affected. Age was presented as 100 percent ranges

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0221

and mean ages for seven auricular surface stages. The age ranges reflect variation in auricular surface appearance and as a result are very wide. While this increases accuracy compared to the Lovejoy method, these ranges are imprecise. The revised method included a Bayesian analysis of the data, assuming a uniform prior probability of age, thus removing the biases introduced by the reference sample (Christ Church, Spitalfields), which is skewed towards older ages.

Tests of the methods have shown that the auricular surface seems to vary little between the two sexes and different ancestry groups. Population-level differences are observed, but this is probably partially a result of the comparison of known age against reported mean age estimates (which reflect the age structure of the reference sample); unless the reference sample and the target population have a similar age-at-death structure, high levels of bias and inaccuracy will be evident. Bayesian statistics have been used to develop paleodemographic profiles (see PALEODEMOGRAPHY AND HAZARDS ANALYSIS) that are not influenced by the age structure of the reference sample and have been used successfully to investigate catastrophic mortality during the Black Death and to compare archaeological populations in Japan (for example).

The auricular surface was included in transition analysis (see ESTIMATING ADULT AGE: TRANSITION ANALYSIS). In this method, auricular surface traits are particularly useful for estimating the age of older individuals, and the trait “posterior iliac exostoses” specifically has been noted as a trait of old age. Attempts to apply auricular surface age estimation to 3D images have had limited success and it is likely that new methods would need to be developed to apply to 3D models of auricular surfaces, as many features (grain, striae, microporosity) are hard to capture using laser scans or computed tomography (CT) scans. Future research should address more robust statistical methodologies for

combining age-related data, estimating individual age, and presenting the probability of age of an individual.

Estimating Adult Age: Pubic Morphology

ROSANNE BONGIOVANNI and KELSEY
C. HENTSCHEL-FEY

University of South Florida, USA

A number of techniques are commonly employed for estimating age at death such as epiphyseal fusion, cranial suture closure, dentition (formation, eruption, and attrition), and age-related changes to the pubic symphysis, auricular surface, and sternal rib ends (Garvin et al. 2012). The pubic symphysis is the cartilaginous joint found in the midline on the anterior plane connecting the right and left halves of the pelvis. It is considered the most reliable skeletal age indicator and is therefore the most frequently applied technique (Garvin et al. 2012). Morphological changes that occur on the pubic symphysis appear to travel along a distinct seriation that is irreversible. Moreover, these changes occur throughout one's lifetime, well into old age, whereas many skeletal age-estimation techniques such as epiphyseal fusion and dental formation are only used to estimate the age of subadults.

Age-related changes of the pubic symphysis were first documented in 1920 by Todd. Todd (1920) generated a ten-phase system, with each phase defined by a morphological description paired with an age range. The early phases describe post-adolescence when the pubic symphysis expresses billowing, followed by the changes that occur throughout middle-aged adults such as definition of the upper and lower limits of the face, filling in of the ridges and furrows, and the formation of a symphyseal rim. The final phase encompasses all individuals 50 years and older, when features are no longer developing but rather degenerating. This final phase is defined by the breakdown of the symphyseal rim, erosion of the symphyseal face, and lipping along the margins. Todd (1920) concluded that the rate of degeneration was not associated with

differences between ancestries or sexes, and the variation observed on female pubic symphyses was not due to the effects of parturition, or childbirth.

McKern and Stewart (1957) argued that the phases put forth by Todd (1920) were too specific and the age ranges too narrow to accurately capture the variation observed at each age. They proposed a component system based on the dorsal plateau, ventral rampart, and symphyseal rim that generates a composite score, which is connected to age ranges. This three-component system was later concluded to be applicable to a female sample; however, this method seriously underestimates the age of older skeletons of both sexes, and is therefore no longer widely used (Garvin et al. 2012).

Katz and Suchey (1986) believed the McKern and Stewart method proved too difficult to utilize for an inexperienced analyst and decided that a six-phase system derived from the original ten phases from Todd performed most accurately. Then, Brooks and Suchey (1990) acknowledged the need for a female standard because of the morphological differences due to parturition. The individuals in their sample consisted of males and females derived from four different continents and various socioeconomic backgrounds. Thus, the Suchey–Brooks method is a six-phase, sex-specific method for age estimation using the pubic symphysis, and is the most commonly used today. Accuracy of this method is dependent on an observer's ability to accurately assign a numerical phase to various morphological changes observed on the pubic symphysis (Garvin et al. 2012).

In order to combat issues with age-mimicry and small sample sizes, the field of age estimation is moving from description of phases to transition analysis (see ESTIMATING ADULT AGE: TRANSITION ANALYSIS). Transition analysis utilizes a Bayesian approach (see BAYESIAN STATISTICS) for skeletal age estimation by using uniform priors and likelihood functions to make inferences on the timing of the transition from one phase to the next. This method helps better identify older age

cohorts, which historically has been a limitation of earlier methods because the last phase is the largest, most encompassing phase. Transition analysis returns to using a component-based system, but attaches a statistical probability of that individual being in each of the expressed phases for each component, given that population (Boldsen et al. 2002). Transition analysis is ideal for single skeletal age indicators such as the pubic symphysis because the currently employed techniques are defined by discrete stages where no specific set of features are repeated (Boldsen et al. 2002; Garvin et al. 2012).

Accurate estimation of age relies on the assumption that the individual being analyzed is biologically similar enough to the reference population to follow the same rate of degenerative change. As a result, recent studies promote the need for population-specific standards that focus on specific combinations of age, sex, and ancestry (Garvin et al. 2012). Additionally, the application of statistical methods such as transition analysis to age-estimation techniques continues to progress the field. With a focus on improving and increasing accuracy, research on pubic age estimation continues to expand worldwide.

Estimating Adult Age: Transition Analysis

JESPER L. BOLDSSEN

University of Southern Denmark, Denmark

GEORGE R. MILNER

Pennsylvania State University, USA

Transition analysis is a statistical procedure designed to estimate the age of human skeletons. At present, this approach has been applied to adult skeletons, although nothing prevents its extension to juveniles. Introduced by Boldsen and colleagues (2002), transition analysis addresses difficulties with standard procedures first identified by Bocquet-Appel and Masset (1982) that result in biased age estimates. Problems with commonly used adult age-estimation procedures are so pervasive that no confidence can be placed on age-specific mortality patterns, life expectancy, or longevity generated from them.

There are two ways to collect age-related skeletal information. Entire anatomical structures, such as the pubic symphysis, can be arranged in a sequence of stages from young to old. The observer essentially integrates various age-informative features when deciding which stage most closely matches the specimen of interest. Alternatively, different aspects of an anatomical structure are scored as separate components, and the resulting information is combined through a formal analytical process. Transition analysis is an analytical, component-based approach to age estimation based on the pubic symphysis, sacroiliac joint, and cranial sutures.

In standard procedures, a skeleton's age is estimated directly from the age distribution of individuals assigned to a given stage in the reference sample. The resulting age-mimicry seriously biases estimates of age for individual skeletons and undermines paleodemographic findings (Bocquet-Appel and Masset 1982). That problem is avoided in transition analysis by estimating the

probability of being in a given stage conditional on being each age (e.g., each year) throughout the human lifespan ($P(stage|age)$). First, the age-at-transition from one stage to the next is estimated through sigmoid curves (Boldsen et al. 2002). Sigmoid curves permit the identification of the mean age of transition and confidence intervals, assuming a symmetrical distribution around the mean. A stage-specific likelihood function is estimated by subtracting the probability of having entered the next higher stage at any age from the probability of having entered the stage in question. These likelihood functions, one for each stage, are not affected by the reference sample's age distribution. However, a sufficient number of skeletons spread throughout adulthood is needed to generate curves with sufficient confidence for age estimation.

The likelihood functions for different components are then combined to estimate the age of a skeleton given that it was assigned to a particular multivariate stage ($P(stage|age)$). That is, the age of a skeleton from an archaeological or medicolegal context is estimated by combining the probability distributions for each observed trait. This procedure yields the probability that an individual was a particular age, the following year, the next one, and so on.

For each skeleton, a point estimate (maximum likelihood) is produced and, of more interest, an age range. Estimates are only valid if conditional independence can be assumed. Boldsen et al. (2002) provided an ad hoc solution, but a mathematically satisfactory solution awaits further research. Furthermore, the estimates described above are generated assuming there was an uninformative, or uniform, prior distribution. The estimates can be modified for forensic and archaeological purposes by applying different prior distributions corresponding to mortality regimes characteristic of appropriate populations (e.g., United States homicides for forensic cases).

The use of sigmoid curves for each trait will work well for juvenile and young adult skeletal features that are strongly influenced by developmental processes, such as tooth

formation. Ongoing work with skeletal features related to senescent changes in adults, however, indicate that smoothed empirical transition curves might better characterize what has been observed in large and diverse skeletal samples.

In its current form, transition analysis works better than any other age-estimation procedure for adult skeletons. That still leaves much to be desired because individual estimates are often wide of the mark, and specific ages for the elderly are largely unsupported because there are few old-age indicators (Milner and Boldsen 2012). Together, however, the estimates approximate the true age-at-death distribution through middle age, although the upper end of the lifespan tends to be underestimated.

Those two challenges—poor individual estimates and an underestimation of old people—are currently being addressed, starting with systematic examinations of several tens of potentially informative age indicators distributed throughout the skeleton. Individually, these skeletal features provide little information about age because they are often classified simply as absent or present (i.e., young or old). Collectively, however, they hold much promise to judge from experience-based appraisals of age based on a large array of such features (Milner and Boldsen 2012). Incorporating these features in a transition analysis framework should yield more accurate estimates and provide a means to narrow age ranges, especially in middle to old age, that are often too long to be of much practical use.

Estimating Skeletal Sex: Cranial and Pelvic Morphology

CORTNEY N. HULSE

University of Nevada, Reno, USA

KYRA E. STULL

University of Pretoria, South Africa

Anthropologists assess and quantify sexually dimorphic features, or features that exhibit differences in size and shape between the sexes, to estimate the biological sex of a skeleton. Even though sexual dimorphism is quantifiable in the subadult skeleton, sexually dimorphic differences are greatest following the pubertal growth spurt. Both the pelvis and cranium exhibit sexually dimorphic morphological features that are used to estimate the sex of unidentified skeletal remains. While metric and nonmetric methods exist, the methodological approach is largely dependent on the element(s) available and their condition. Generally, metric analysis reduces intra- and interobserver error and is more objective, while morphological analysis is more subjective and efficient. Because each case is unique, there is not an exact process to follow. However, one should always use a method that is reliable and valid.

The pelvis is widely recognized as the most accurate element for sex estimation because of the inherent differences due to reproductive requirements. Morphological methods are more common than metric methods for the pelvis, partly because of the problems associated with pinpointing well-defined, reliable landmarks on the pelvis. There are several morphological skeletal features on the pelvis to estimate sex (e.g., greater sciatic notch, obturator foramen, breadth of the pubic bone). A popular feature on the pelvis that contributes to sex estimation, but has received less research focus than other skeletal features, is the greater sciatic notch. The

greater sciatic notch can adequately (80%) separate males and females using an ordinal scoring system ranging from hyperfeminine (score of 1) to hypermasculine (score of 5).

Phenice defined the most frequently analyzed nonmetric traits, which are located on the pubic bone. Phenice traits include the ventral arc, subpubic concavity, and medial aspect of the ischio-pubic ramus. The three traits were assessed for simple presence or absence and yielded overall classifications of 96 percent. While the Phenice method was employed for several decades without modification, the methodology ignored the range of variation associated with the expression of each trait and how to assess the traits if they were ambiguous or inconsistent. Klales, Ousley, and Vollner (2012) revised the Phenice method by including a standardized ordinal recording system and incorporating a logistic regression model to predict the probability of sex membership based on the pelvic trait scores. The cross-validated mean classification rate was 94.5 percent, with low intra- and interobserver error (Klales et al. 2012). Recently, efforts have been made to incorporate contemporary skeletal samples from numerous countries in an attempt to develop a global model. In the event of unknown ancestry, a global recalibration equation increases applicability and the overall probability of a correct classification.

The cranium has historically been considered the second-best indicator and is commonly used in sex estimation by forensic anthropologists and bioarchaeologists. Both metric and nonmetric methods are regularly employed. The most popular statistically substantiated, nonmetric approach combines a five-stage scoring system for five cranial morphological traits (glabella, nuchal crest, mental eminence, mastoid process, and supraorbital margin) and employs discriminant function analysis to obtain correct classifications. Modern populations had classification rates up to 88 percent, while ancient Native American groups had classification rates up to 83 percent (Walker 2008). Recent studies have tested the accuracy of Walker (2008) on numerous contemporary

and historical populations and have proven that the given population on which the method was developed was extremely influential in classification rates. While the Walker (2008) method is effective, it has lower correct classification rates than methods using the pelvis, particularly when applied to other populations. While Walker's method remains frequently employed for its ease of use, further studies are being conducted to increase correct classification rates and better understand the underlying processes and covariation of traits. Such new methods are attempting to quantify shape differences in the previously defined cranial morphological traits. For example, Garvin and Ruff (2012) created a new quantitative methodology to test sexually dimorphic brow and chin morphology utilizing 3D surface scans. Browridge analysis returned a classification rate between 74 and 91 percent, while the chin returned a classification rate of 62–74 percent (Garvin and Ruff 2012).

As with most methods, population specificity is important to recognize prior to employing a method. Even though the effects of population specificity are historically recognized to be more substantial with metric methods, classification accuracies associated with morphological methods decline dramatically when they are applied to populations excluded from the reference sample. This holds especially true with cranial traits. The degree of sexual dimorphism varies around the world and is population dependent. Bioarchaeologists and forensic anthropologists should always

be aware of the population that the method was derived on prior to application.

While there are numerous methods to be aware of, as well as case-specific factors, it is strongly recommended that when estimating sex, emphasis first be placed on morphological analysis of the pelvis and then on metric analysis of the long bones and cranium. As with most aspects of the biological profile, the more elements evaluated and the more methods employed, the more likely a correct classification.

Estimating Skeletal Sex: Metrics

CHRISTINE A. JONES
Texas A&M University, USA

Sex estimation using metrics involves the analysis of single or multiple measurements based on osteological landmarks or on the maximum or minimum dimensions of cranial or postcranial bones that are sexually dimorphic. Analyses using single measurements are known as univariate analyses, and those using multiple measurements are known as multivariate analyses. A simple index may also be used, which is created using two single measurements. For both univariate and multivariate analyses, observed measurements are compared to a distribution of measurements from individuals of known sex and defined population, which results in sex estimations that are highly population-specific.

Both univariate and multivariate metric analyses usually involve the application of discriminant function analysis (DFA). This is a statistical method used to determine which variables discriminate between two or more naturally occurring groups, in this case males and females, and assumes a normal distribution of the sample for each measured trait. Univariate metric analyses and indices rely on a sectioning point calculated using DFA that is then used to reliably categorize males and females into separate groups for a given population. When used to estimate skeletal sex, DFA can utilize several different approaches including canonical discriminant functions and Mahalanobis distances (see STATISTICS IN ARCHAEOLOGY).

The first successful application of discriminant function analysis in sex estimation was a method developed by Giles and Elliot (1963) utilizing multiple cranial measurements, which was found to correctly estimate sex at a rate of 85%. Rates for correct classifications of African Americans and European Americans from the Forensic Data Bank (FDB) at the University of Tennessee range

between 83–93% and give a general indication as to the overall accuracy that can be expected of metric sex estimation using discriminant function analysis (France 1998). While craniometrics are useful, methods that are based on postcranial metrics have been found to show much greater accuracy, according to a comprehensive study of sectioning points based on postcranial measurements from the Forensic Data Bank (FDB) at the University of Tennessee (Spradley and Jantz 2011). Traditionally, methods based on multivariate measurements of the humerus, scapula, femur, and tibia are more accurate, more commonly used, and are supported by more extensive research than methods using other postcranial bones. One important conclusion by Spradley and Jantz (2011) was that the metric analysis of the pelvis, whether univariate or multivariate, was shown to rank lower in accuracy than expected relative to other postcranial bones, in spite of the standard assumption of the pelvis as a reliable indicator of skeletal sex by many anthropologists. One major drawback of using craniometrics and postcranial metrics to estimate sex is the fact that the majority of standards are highly population-specific. Thus, care must be taken in application to skeletal samples that are far removed in ancestry.

Fordisc, a computer program that uses discriminant function analysis, is based on a reference population comprising nearly 3,400 forensic cases from the University of Tennessee's Forensic Data Bank (Ousley and Jantz 2005). Fordisc uses both cranial and postcranial measurements to estimate sex and should only reasonably be applied to samples where the reference population is known to be included in the Forensic Data Bank for the version of Fordisc being used. The program also includes Howells' worldwide cranial data, which allows for greater accuracy in estimation sex, stature, and ancestry of archaeological samples.

Future work in estimation of sex using skeletal metrics involves the refinement of methods using bones that have not traditionally been used for sex estimation or for which few studies have been

attempted at a high level of statistical rigor, such as the patellae, ribs, and vertebrae. More research is also needed in testing relatively new methods that claim to be universal, or independent of specific populations. For example, a recent multivariate method using measurements of the pelvis and femur and logistic regression was able to correctly classify 95–97% of the sample of the population under study. According to the authors, the method is universally applicable as it is based on biomechanical differences between males and females; however, the method has not yet been widely tested (Albanese, Eklics, and Tuck 2008).

Another expanding field of study within metric sex estimation is the application of geometric morphometrics (see GEOMETRIC MORPHOMETRICS) to allow for comparison of measurements based on differences in shape while at the same time accounting for size differences. Geometric morphometrics allows researchers to analyze variability in shape in a more complex way than is possible with linear measurements alone. Geometric morphometric methods utilize 3D scanning, CT scanning, and specialized computer software that allows measurements to be captured across the whole surface, whereas standard metric analysis is dependent on discrete measurable landmarks. In addition, the use of geometric morphometrics may also help reduce the issues with intra-observer and inter-observer error that sometimes accompany metric analysis.

Estimating Subadult Age: Dental Development and Eruption

LORI E. WRIGHT and KRISTIN K. HOFFMEISTER

Texas A&M University, USA

The successive formation and emergence of the deciduous and permanent teeth in the mouth have been used to estimate the age at death of skeletal remains since the earliest forays into mammalian osteology by naturalists. For humans, dental development is traditionally considered to be the gold standard for age estimation of children's remains, and is often used to calibrate other aging methods, such as the comparative study of developing long bone lengths (see ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH) that may be more directly affected by growth arrest or population variation. However, the most widely used standards (Schour and Massler 1940) suffer from significant sampling biases that undermine confidence in the precision of these methods. New standards (Al Qahtani, Hector, and Liversidge 2014), derived from better documented reference collections, show some improvement, as do histological methods that permit individual age estimates from the observation of microscopic internal features of tooth enamel.

Anatomists and anthropologists have long used the progressive emergence of the deciduous or primary teeth into the mouth and their replacement by the larger permanent teeth as a means to estimate age at death or the age of living children. Following the eruption of the permanent third molars at the end of the second decade of life, teeth provide a much less reliable means to estimate age; the wear of the occlusal surfaces of teeth can provide a population-specific broad estimate of relative age among adults, but it is much less accurate than other methods of estimating the age at death of adults.

The Schour and Massler standards

Pictorial representations of dental formation and eruption were first developed in the nineteenth century. These early chronologies were based on observations of developmental defects known as enamel hypoplasias. In the early twentieth century, Logan and Kronfeld dissected the teeth of deceased infants and fetuses to document dental development. Many of their subjects had died from infectious conditions or experienced developmental anomalies, so it is possible that their growth may have differed from that of healthy peers who survived childhood. However, dental development does appear to be under strong genetic control, and short-term developmental arrest causes little disruption to the chronology of tooth development overall. Schour and Massler (1940) modified this work by incorporating further evidence from the patterning of hypoplasias on tooth enamel. Schour and Massler's pictographic atlas of dental development continues to be used by many researchers for estimating the age at death of subadult remains and is pervasive in dental textbooks. This atlas shows the chronology and sequence of dental development and eruption in stages that are associated with chronological age ranges. The 21 stages of development in this chart depict the changes in dental development and eruption from five months in utero to 35 years of age. While the Schour and Massler (1940) standards are widely used, these early works were based on very small samples of children of European ancestry alone. In addition, later radiographic studies carried out on diverse populations show some population variability in eruption timing and sequence. Subsequently, Ubelaker published a minor modification of the Schour and Massler chart that he adjusted to better conform with eruption patterns described by radiological studies of Native American children. Ubelaker's chart is most commonly used in bioarchaeological studies in the Americas. Many bioarchaeologists also score the state of dentine, enamel, and root development on incompletely

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0227

formed teeth as a more precise record of dental formation in subadult dentitions.

The London Atlas

More recently, Al Qahtani et al. (2014) have developed a dental development and eruption atlas that can be used to estimate the age at death for individuals between 30 weeks in utero and 23.5 years of age. This “London Atlas” is an improvement over earlier standards because the reference populations and methods are well documented; the atlas was based on a large series of radiographs, as well as prenatal and postnatal known age historical skeletal remains from London. The London Atlas is comprised of 31 stages of dental development that include more detailed depictions of tooth development, including the progression of enamel, dentine, and pulp. It appears to be more accurate than the Schour and Massler chart, although the London Atlas has not been widely tested for skeletons that are not of European origin.

Dental histology

Developmental features within tooth enamel are now understood to result from circadian fluctuations in the activity of ameloblasts, which are cells that produce enamel. Daily cross-striations and circaseptan striae of Retzius are visible in longitudinal thin sections cut from teeth, and

Retzius striae outcrop onto the surface of teeth as fine ridges known as perikymata. These features can be counted to document crown formation times for individual teeth. Although histological studies show systematic population variation in the duration of amelogenesis, or the formation of enamel, they also confirm narrower ages for the onset and conclusion of enamel formation than indicated by radiographic data (Reid and Dean 2006). While labor intensive, enamel histology can be used to estimate age at death very precisely for skeletons of children who died prior to the end of enamel formation.

Estimating Subadult Age: Diaphyseal Length

CHARLOTTE PRIMEAU
University of Dundee, UK

Age estimation is the first key step in the study of archaeological subadults (juveniles, non-adults, children) in bioarchaeology (see *BIOARCHAEOLOGY*). Subadults are defined differently between researchers and can include individuals aged up to 17–19 or even 21 years. The chronological age (actual age) of skeletal subadults is generally unknown, with the exception of skeletal collections with a documented age from coffin plates. When the age is unknown, it is the biological age that is estimated. The biological age of archaeological subadults can be estimated either from dental development (see *ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION*) or skeletal development. Skeletal age can be estimated from appearance and maturation of the skeletal elements, timing of fusion, or length of long bones (diaphyseal lengths). Estimating the age of subadults allows analysis of changes in mortality and morbidity between age groups, as well as studying the effects of an adverse environment on growth (when compared with dental development) to reconstruct life histories of past subadult populations.

Estimating the age of subadult skeletons using diaphyseal lengths is less accurate than using dental development, since long bone growth is more influenced by adverse conditions such as periods of disease, malnutrition, or starvation. In addition, nutrition and infection act in synergy where children with suboptimal nutrition are more prone to contract infections, while infectious disease may lessen nutritional uptake. More importantly, height among children is variable, even if they are from the same population and develop under the same living conditions, which is evident when looking at any modern group of same-aged children. Additionally, age estimation from diaphyseal lengths will be less accurate the

older the subadult, especially when approaching puberty. During puberty, sexual dimorphism increases due to differential hormone secretion, and this results in dissimilar adolescent growth spurts between the sexes, with girls completing their growth (fusion of epiphyses) up to two years earlier than boys. Therefore, estimating age from diaphyseal lengths is less precise than dental age and carries a greater error range, especially for older subadults (i.e., in the pubertal years). Despite these issues, estimating age from diaphyseal lengths is still useful when working with subadult remains, as there will always be cases where there is no dental information available due to taphonomy or fragmented remains. In cases with commingled remains (see *COMMINGLED HUMAN REMAINS*), diaphyseal lengths can be used as an age indicator to establish relationships between dispersed subadult parts.

Estimating age from diaphyseal lengths requires the length of the diaphysis to be compared with a known standard or an established method such as table data or regression equations. Scheuer and Black (2000) compiled several known standards of table data. The table data were predominantly derived from radiographic images from children living in the mid-twentieth century. The issue with applying such data to archaeological subadults is two-fold. Firstly, there is a difference in growth patterns between a modern population and those of an archaeological population. Secondly, a bias arises from differences in methodology when applying measurements from radiographic images to those of archaeological dry bone due to image magnification and shrinkage of dry bone. In addition, the individuals from the table data (Scheuer and Black 2000) were generally healthy, whereas deceased archaeological subadults may well have experienced compromised growth.

More recently, methods for estimating age from diaphyseal length have been explored and are generally presented in two forms: cross-sectional studies on archaeological material of known age (i.e., documented age from coffin plates), and cross-sectional studies on

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0228

archaeological material of estimated age. Both types of study generally present their method as regression equations. Regression equations can be used to calculate a predicted age based on the measurement of the length of long bones. The advantage of using a documented sample of known age and sex is that the developed method will have a known accuracy. However, there are a limited number of subadult skeletal collections of documented age, and these tend to date from the eighteenth, nineteenth or twentieth centuries. The disadvantage of methods devised on this more recent material is that they might not be transferrable to older archaeological populations or those from geographically distant populations. This is due to discrepancies between chronological and skeletal age between populations, as well as different growth opportunities. The advantage of using methods devised on archaeological materials of estimated age is the possibility of larger sample sizes (depending on the time period), as well as the methods being population-specific and contemporaneous to the archaeological remains being investigated. The disadvantage is that the accuracy of the method is unknown. Using table data from modern children as referenced in Scheuer and Black (2000) raises the issue of “biological mortality bias” where growth data from living healthy subadults (survivors) is unlike to represent growth of subadults that died prematurely with potentially compromised growth due to malnutrition and disease. Therefore, methods developed from a modern population of subadults (survivors) would be inappropriate to use for an archaeological population of deceased subadults. Hence, when choosing a method for archaeological material, it should reflect the population under investigation in environmental conditions, time period and geography. It can therefore be from archaeological subadults of

either known or unknown age, depending on the history of the population being examined.

Future directions for estimating age from diaphyseal lengths may derive from development of newer reference data from cross-sectional studies using CT images of clinical data. However, such studies will not circumvent the problem of using aging methods developed on subadults from distinctively different environments and time periods to estimate the age of archaeological material. Therefore, data from present-day material would mainly be applicable to forensic cases rather than archaeological material.

Estimating Subadult Age: Epiphyseal Union

NICHOLAS V. PASSALACQUA
Western Carolina University, USA

Whether the age at death is estimated for a single individual as part of a biological profile, or for a group of individuals seriated against each other, the estimation of the age at death from subadult skeletal remains (all individuals that are still undergoing the biological processes related to growth and development) is a routine part of skeletal analysis for bioarchaeology, paleodemography, and forensic anthropology. Using epiphyseal union is one of the primary techniques used to estimate the age at death of subadult remains, the others being dental development and eruption, and long bone growth.

Generally, all bones grow and develop through intramembranous or endochondral ossification, with some elements using both mechanisms (Scheuer and Black 2000). Intramembranous ossification involves bones growing and developing within a mesenchymal membrane (e.g., the bones of the cranial vault, such as the parietal), while endochondral ossification involves bones growing and developing from a cartilaginous model (e.g., the femur). Both mechanisms of bone growth rely on ossification centers, or areas from which bone is deposited and remodeled as it grows. The concept of epiphyseal union is primarily used for assessing the completion of various areas of bone growth using the postcranial bones (i.e., all bones except those found in the skull).

Most of the postcranial bones in the human body grow and develop from primary and secondary ossification centers. The primary ossification center serves as the main platform or structure of the bone, while the secondary ossification centers, or *epiphyses*, serve as peripheral areas of bone growth. Using the femur as an example, the primary ossification center is located in the femoral diaphysis, and there are four secondary ossification centers which are

found at the femoral head, greater trochanter, lesser trochanter, and distal end of the femur (Scheuer and Black 2000; Figure 1). When ossification centers fuse together, they form a single bony structure; this unity of ossification centers is referred to as *epiphyseal union* and reflects the end of a particular growth process, with different epiphyses uniting at different ages. Generally, ossification centers serve as the main areas of bone growth and development during the fetal, infant, and childhood periods, while it is the junctions between the primary and secondary ossification centers (i.e., growth plate or physis) that account for interstitial bone growth, and associated increases in bone length and stature during childhood and adolescence (Scheuer and Black 2000).

Most epiphyses unite between the ages of 10 and 25 years, making epiphyseal union a reliable method for estimating age for individuals in adolescence or young adulthood. While there have been a large number of investigations regarding the growth and development of the human skeleton and epiphyseal union, perhaps the earliest detailed examination of epiphyseal union was performed by Flecker (1942). However, it was not until 1957 that McKern and Stewart published their seminal work relating to age-at-death estimation from epiphyseal union. In this work, McKern and Stewart (1957) systematically analyzed identified male deceased United States military service members from the Korean War. In their publication, McKern and Stewart defined five stages (e.g., 0–4) of epiphyseal union and presented tables with the timing of each stage for most major epiphyses in the human body for male individuals aged 17–24+ years. This study was followed by many others including Webb and Suchey (1985), who investigated the epiphyseal union of the iliac crest and medial clavicle using a large sample of identified female and male individuals from the Los Angeles medical examiner's office, providing standards for the epiphyseal union of these areas for individuals with ages ranging from 11–40 years of age. In 2000, Scheuer and Black published *Developmental Juvenile Osteology*, a detailed and

well-illustrated reference work compiling growth and development standards, including those for epiphyseal union for all the bones in the human body. In 2009, Schaefer and colleagues presented an updated and truncated version with simplified tables of epiphyseal union for females and males.

The process of initial union to final epiphyseal closure may last several years. Because of this, most methods for assessing epiphyseal union use a scoring system that evaluates the degree of union on an ordinal scale from no union present to complete union. Generally, epiphyseal union begins in the center of the epiphyseal junction and radiates out from there. Therefore, the process of epiphyseal union is typically scored based on the presence and extent of the epiphyseal line, which is a distinct area visible between the two components (typically the primary and secondary ossification centers) and tends to obliterate through remodeling over time. While the estimation of age from epiphyseal union can be performed using radiographs or dry bones, methods developed on one type of material

(e.g., radiographs) may not be directly applicable to another based on differences in observable features and scoring systems; thus validation of method application between analytical materials should always be performed prior to use.

The timing of epiphyseal union between males and females is different, representing differences in growth and development primarily related to puberty and the development of secondary sexual characteristics and the adolescent growth spurt. Additionally, it is important to remember that while the timing and sequence of growth and development processes are fairly rigid due to our evolutionary history, small yet significant differences in the timing of epiphyseal fusion have been found between different populations (Langley-Shirley and Jantz 2010). While much of this variation is due to differences in nutrition, activity, socioeconomic status, and/or secular changes, it means that methods developed on one reference sample should be applied with caution to populations with different life histories.

Food Residue Analysis

LUCY J. E. CRAMP

University of Bristol, UK

Residues resulting from the processing, storage, and/or consumption of food in the past can be preserved in the archaeological record in a variety of forms. Very rarely, in-situ vessel contents may be preserved, such as wooden vessels containing “bog butter” or sealed containers with the contents still held within. More frequently, visible traces of food residues may be found in association with artifacts, preserved usually through carbonization. This includes deposits adhering to cooking pots, resulting from the burning of foodstuffs during cooking. Finally, and most widespread, are nonvisible traces of foodstuffs that may be protected and preserved in association within an archaeological matrix such as ceramic or stone artifacts. Useful biomarkers (biological markers) from such residues can be very well preserved under favorable conditions, but their presence would not be detectable with the naked eye.

The origins of amorphous organic food residues can be determined using a variety of analytical techniques (see CHEMISTRY IN ARCHAEOLOGY and CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS). All rely upon the same principle, that of identifying one, or a suite of, diagnostic biomarkers that can be unambiguously related to a source. Some of the most widely preserved organic compounds may be ubiquitous in origin. However, careful assessment of the entire composition of potential sources, which takes into account predictable degradative and post-depositional processes, can lead to the identification of diagnostic “fingerprints” based upon the survival of unique markers or distributions of markers.

Organic foodstuffs are comprised predominantly of lipids, carbohydrates, and proteins in varying proportions. The survival of these different classes is not equal; in general, the

hydrophobic (not water soluble) and relatively recalcitrant nature of lipid molecules (fats and oils, including fatty acids, waxes, and sterols) means that these survive widely, especially when protected within a ceramic matrix, although variability will be dependent on localized environmental and climatic conditions. Carbohydrates, including simple sugars and polysaccharides (e.g., starches), are more susceptible to leaching, mobility, and loss within the soil profile. Ancient proteins, while relatively soluble in water, have exceptionally been identified, primarily through immunological techniques, and, more recently, through larger-scale (proteomics) approaches using mass spectrometric methods to residues from artifacts and dental calculus using tandem mass spectrometry.

The earliest investigation of the origins of preserved lipids from organic food residues dates back to the 1970s when Condamin and co-workers investigated the fatty acid composition of extracts from Roman amphora from the Mediterranean using gas chromatography–mass spectrometry (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) (Condamin et al. 1976). While this approach was in its infancy, the distribution of fatty acids led the researchers to attribute these residues to olive oil (see OLIVES AND OLIVE OIL). In the early 1980s, Morgan et al. (1983) investigated the fatty acid composition of “fatty materials” from a Thule settlement in northwest Canada, drawing comparisons with fatty acid compositions of modern marine mammal fats. This study highlighted that the highly unsaturated fatty acids, present in modern marine fats, were absent from the archaeological residues and, hence, a fundamental principle of the study of ancient food residues: that various degradative processes, such as thermal degradation, microbial activity, and leaching, need to be anticipated, and accounted for, before archaeological biomolecules can be assigned to a potential source.

Since these early studies, considerable research has been performed to better understand the degradation pathways of lipids in food residues

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0246

undergoing cultural processes such as heating, as well as processes arising post-depositionally. This has confirmed not only the loss of more unstable components such as unsaturated fatty acids but also the transformation of labile lipids to more stable degradation products that may have significant interpretative value. Thus, for example, distinctive distributions of mid-chain ketones are now understood to form through the heating of animal fats within a ceramic matrix, while a series of relatively stable markers arise from the thermal degradation of polyunsaturated fatty acids characteristic of marine fats and oils (see Roffet-Salque et al. 2016 and references therein).

The fingerprints of lipids from food residues can differentiate foodstuffs originating from a variety of sources, including animal fats, plant epicuticular (surface) waxes, plant oils (see OILS AND FIBERS), and insect waxes (i.e., beeswax, associated with honey exploitation). Fats originating from animal products are usually most widely recovered, likely due to not only the widespread cooking or processing of animal products, but also their relatively high lipid content compared with other types of food products. Lipid distributions characteristic of degraded animal fats can be relatively distinctive, comprising saturated fatty acids and characteristic ranges of triacylglycerols (triglycerides) and their degradation products. However, assigning these fingerprints more specifically to their origins usually relies upon the determination of the stable carbon isotope composition of the major fatty acids that are preserved. This stable isotope signature records the metabolic and dietary origin of the carbon and therefore can be used to discriminate between animal fats of ruminant and nonruminant origin (e.g., separating cattle, sheep, and goats (see SHEEP AND GOATS) from pig (see PIGS) or horse, and terrestrial from marine or freshwater species. Importantly, differences in the biosynthesis of fatty acids in the mammary gland of ruminants means that fats of dairy origin can also be separated from carcass (meat) fats from the same species. This approach has enabled large-scale questions regarding the origins and timing of animal secondary products exploitation (e.g., see Roffet-Salque et al. 2016 and references therein) to be targeted (see DOMESTICATION AND DAIRYING). Currently, the separation of fats from different species within ruminant groups is

challenging; however, the composition of exceptionally well-preserved triacylglycerols using nanoelectrospray ionization mass spectrometry (see MASS SPECTROMETRY (MS)) has shown the ability to distinguish fats from cattle, sheep, and goat (Mirabaud, Rolando, and Regert 2007).

Lipid residues of plant food origin are somewhat less widely recovered, but include long-chain aliphatic compounds originating from plant leaf waxes, as well as phytosterols and terpenoids. Plant oils, characterized by higher abundances of unsaturated fatty acids and phytosterols, have been identified from culinary and other contexts (e.g., used in mummification or lighting). Some types of plant oils, such as date palm oil, Brassicaceae (including mustard, radish, and rapeseed) oils, and castor oil, have unique or unusual markers, enabling a relatively specific identification of origin. However, others, such as olive oil, are not yet known to possess sufficiently specific markers that will survive over archaeological timescales. Wax from bees has a distinctive and recalcitrant distribution of *n*-alkanes, *n*-alkanols, and palmitate wax esters. Through tracing of beeswax residues preserved in ancient pottery, the paleoecological spread and exploitation of honeybee products by Old World agriculturalists has been demonstrated (see Roffet-Salque et al. 2016 and references therein).

While possessing the potential to provide a higher level of species-specific identification, protein residues from cooking, killing, or butchery of resources have posed significant challenges to identify in practice. Considerable doubt has been cast upon the identification of blood proteins adhering to lithic artifacts based upon hemoglobin crystallographic techniques or immunological reactions, due to a lack of reproducibility, contamination, and, for the latter, cross-reactivity, producing findings at significant odds with the archaeological and environmental context. The analysis of archaeological protein residues from pottery vessels has also been challenged by not only seemingly rapid degradation and hydrophilicity, but also apparently limited transfer of proteinaceous material into the clay matrix (Evershed and Tuross 1996) and/or difficulties extracting molecules that appear to be strongly bound to a mineral surface such as ceramic (Craig and Collins 2002). A

novel digestion-and-capture extraction technique followed by immunological analysis using a monoclonal antibody raised against bovine α -casein has been developed, enabling positive extraction and identification of ancient milk proteins from archaeological sherds and ethnographic dairying pots, which were not detected in negative controls (Craig et al. 2000). More recent approaches to identify archaeological proteins employ shotgun proteomics using liquid chromatography–tandem mass spectrometry. This has so far detected the whey protein β -lactoglobulin trapped in ancient human dental calculus widely among dairying populations, but found it only at low prevalence or absent in societies with a low or declining history of dairying (Warinner et al. 2014).

Carbohydrates, or saccharides, include highly soluble simple sugars through to complex polymeric molecules such as starch and cellulose. Starches, although insoluble in (cold) water, are susceptible to enzymatic attack, which breaks them down into their water-soluble sugars, and therefore they readily degrade in the burial environment. However, in protective conditions such as small cavities in stone tools or grindstones, starch granules (see STARCH GRANULE ANALYSIS) may survive over archaeological timescales, and ancient processing of cereals, roots, and other plants has been identified archaeologically, based upon morphological characteristics shared with modern specimens. Although more specific identifications have been reported, identification beyond genus level is usually not achievable through this approach. Heating of starch during processing (i.e., cooking) will initiate gelatinization, with retrogradation upon cooling resulting in an enzymatically more stable, but morphologically altered, structure. The effects of diagenetic alteration upon the morphological state of ancient granules must therefore be taken into account. With wider concerns regarding the possible contamination of archaeological artifacts with modern starch granules, recent attention has turned to starch trapped in ancient dental calculus as a protective and contextually secure matrix preserving biochemically unaltered starch granules (Hardy et al. 2009).

Genetics: Ancient

ESTHER J. LEE

Texas Tech University, USA

Characterization of human genetic variation has expanded our understanding of human history and evolution in recent decades, providing a unique perspective in understanding past demographic processes. Applying genetic analysis to the remains of once-living organisms can obtain information directly from the past. Thus, we now have a direct tool to reconstruct specific patterns of genetic variation among past populations and are able to understand the patterns within the context of the sociocultural, historical, and environmental settings informed by archaeological data.

DNA analysis targets specific regions of the nuclear and mitochondrial genome. The majority of biological functions are governed by genes on the nuclear DNA. The nuclear genome consists of more than three billion nucleotides that are organized in 23 pairs of chromosomes, including the sex chromosomes X and Y (see *CHROMOSOMAL DNA*). However, mitochondrial DNA (mtDNA), a separate genome of the cellular organelle mitochondrion, has a higher copy number than nuclear DNA and has become an important source of genetic analysis applied to archaeological contexts (see *DNA: MITOCHONDRIAL*). While the nucleus exists in a single copy per cell, there can be as many as a few dozen mitochondria, which translates into a greater likelihood of success when amplifying specific DNA regions from archaeological specimens.

More than 30 years ago, publication of a mitochondrial DNA sequence from the extinct quagga, a subspecies of the plains zebra, ushered in the field of ancient DNA research. The invention of polymerase chain reaction (PCR) further propelled the field, allowing fragmented DNA molecules from organic specimens to be copied a million fold. Once a sequence was obtained from ancient remains, it became possible to make

comparative analyses with the larger population or species. The earliest ancient DNA studies focused on extinct specimens, primarily to understand evolutionary processes. Soon after, studies applied genetic analysis to hominin remains, such as Neandertals, revealing new information on human origins and adaptations. Specific genetic variants involving speech and pigmentation identified from Neandertal remains present information on modern human-specific adaptations. Other genetic variants have been implied in various medical conditions. Now more recent technologies are exploring genetic contributions from ancient hominins to modern humans, such as studies of the remains from the Denisova Cave (see *DNA: NEXT GENERATION SEQUENCING*).

Ancient DNA analysis can address a range of archaeological questions. One significant contribution of ancient DNA analysis is to enhance bioarchaeological investigations seeking to provide information regarding an individual's biological and cultural identity and affinities. An individual's sex can be identified by targeting a sequence on the amelogenin gene present on the X and Y chromosome. DNA identification of sex may either complement the osteological analysis or provide information when the skeletal data is unavailable. Additional markers on the nuclear DNA allow a genetic profile similar to that used in forensic investigations, so that not only can individuals be identified among commingled remains but familial relations may be elucidated in a burial context and genetic ties between the remains and living descendants may even be revealed. In the absence of nuclear DNA, the maternally inherited mtDNA can also clarify genetic relations, albeit at a deeper ancestral level instead of closer familial ties. Without a doubt, information regarding genetic relations can address broader questions concerning the social organization of past populations including aspects of kinship, descent and lineage, and marriage patterns.

As mtDNA represents ancestral maternal lineages and can reveal population patterns at a deeper time scale, ancient mtDNA studies seek to

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0253

explore demographic processes involving genetic continuity and examine patterns of genetic affinities and variation across broader geographical regions. The Mesolithic–Neolithic transition in Europe has been characterized by a distinct genetic pattern between hunter-gatherers and agriculturalists based on the analysis of human remains from the region. Ancient DNA studies have examined genetic continuity after the collapse of the Andean Wari empire and have revealed patterns of specific demographic processes of the Vikings. Studies have also illustrated genetic patterns associated with ancient expansions of specific cultural or linguistic groups in North America, such as the Numic-speaking Native American groups in the Great Basin. Genetic analysis of historical human remains from burials and cemeteries have provided another dimension to the sociopolitical processes involving the African diaspora and the American slave trade by using genetic affinities to populations from specific geographical regions.

Genetic analysis of past populations can also contribute to the discussion of health and disease patterns. Lactase persistence, the ability to breakdown lactose in milk after childhood, is a genetic trait that is absent in most mammals. Among humans however, the frequency of lactase persistence reaches 70–80 percent in some populations. The origin of the genetic variants responsible for lactase persistence is currently debated but has been associated with the advent of dairying practices since the trait is more common among populations with a long history of dairying (see DAIRYING). Ancient DNA analysis of human remains from the earliest agricultural groups to remains from the medieval period is revealing a rapid selection process for the trait (Krüttli et al. 2014).

Paleopathological studies based on osteological analysis have been central to understanding the morbidity and mortality of past populations (see PALEOPATHOLOGY). Genetic analysis has allowed the possibility to identify genetic diseases among past individuals such as thalassemia. Infectious diseases are caused by different types of pathogens each with unique characteristics and adaptations. Many pathogens have a long history of coevolution with humans and have left a substantial mark on human history. Differential diagnosis of skeletal pathology can be

quite difficult from lesion morphology alone (see DIFFERENTIAL DIAGNOSIS). Ancient DNA analysis successfully identified certain bacterial diseases, such as tuberculosis, from human remains. Caused by a cluster of bacterium species known as the *Mycobacterium tuberculosis* complex, tuberculosis has been the most successfully identified pathogen from human remains. Studies have shown the evolutionary history of the disease in the Americas and Europe (Harkins and Stone 2015). Other diseases, including leprosy caused by *Mycobacterium leprae* and the bubonic plague caused by *Yersinia pestis*, have also yielded DNA from human remains. Further whole genomic analysis is revealing phylogenetic information about the various strains that has implications for modern epidemiology and pathogen evolution (see GENOMICS: ANCIENT).

Genetic analysis has also been utilized to trace the origins and spread of domestication of plants and animals by distinguishing wild and domesticated species and by characterizing the variation obtained from various archaeological contexts. While the origin of domesticated wheat grains, such as emmer (*Triticum dicoccum*), einkorn (*T. monococcum*), and spelt (*T. spelta*), is not clearly resolved, genetic analysis has been utilized to distinguish wheat species from charred archaeological remains and to trace the dispersal of wheat cultivation. As a principal domesticate crop of the New World, DNA analysis of maize (*Zea mays mays*) remains show two separate expansions of the crop from Central America into South America (Freitas et al. 2003). Crop origins and their dispersals have also been characterized for domesticates including rice (*Oryza sativa*), potatoes (*Solanum tuberosum*), beans (*Phaseolus vulgaris*), and grapes (*Vitis vinifera*). Ancient DNA analysis of wild and domesticated bovine (*Bos taurus*) and swine (*Sus scrofa*) remains have revealed a process of dispersal linked to the cultural interaction of different groups from their origins in the Near East across Europe. Genetic investigation of the domestic dog (*Canis lupis familiaris*) shows a complex process of domestication that possibly occurred in multiple regions. Any ancient DNA analysis is based on understandings of modern variation and in order to discern wild and domesticated plants and animals, information on modern genetic variation becomes even more crucial.

Recent genetic studies have utilized a wide range of organisms to understand past human environments. While early studies were most successful at obtaining DNA from bone specimens, recent developments have extended the types of samples for DNA analysis. Ancient DNA research is not necessarily restricted to vertebrates, but can include arthropods, worms, a range of plant components (wood, pollen), and various microorganisms. DNA can be deposited by an organism's skin flakes, urine, feces, eggshells, and saliva. These traces of DNA have been obtained from a variety of environments including lake cores, surface soils, and cave sediments that allows data regarding past biodiversity and the environmental settings that past humans inhabited (Pedersen et al. 2015). The importance of human environments is central to the study of human microbiomes, referring to the collection of microbial genomes present in humans. The composition and variation of microbiomes among human populations have been implicated in health and diseases, and analyses from human remains are providing novel insights into the diet and broader ecological environments of past societies (Warriner, Speller, and Collins 2015). Current research analyzing RNA transcripts, processed copies of DNA segments, from ancient maize kernels may further shed insight on the external environmental conditions of domestication. Research on the methylation of DNA in ancient specimens may provide yet another window into understanding epigenetic changes that underlie crucial developmental processes, which are also implicated in diseases among humans (Smith, Monroe, and Bolnick 2015). Expanding the scope of specimens for DNA analysis can broaden the types of research questions addressing the lives of past populations and allow for fruitful collaborations among a wide range of specialists within and beyond the archaeological sciences.

Techniques for sequencing and extracting low quantities of DNA from degraded specimens continue to improve, extending the limits regarding the age and quality of information obtained. Nevertheless, limitations still exist relating to the cost of analysis and factors of DNA degradation. Degradation of DNA occurs after the organism's death and continues from in situ to post-excavation, influenced by temperature,

water, oxygen availability, and microbial activity among others. It remains difficult to obtain autosomal data or STR profiles to infer familial relations within a burial context, and when mtDNA data is available one must understand that the genetic relations inferred come from a maternal ancestor shared by thousands of people. Still, the development of techniques for ancient genetic analysis will continue to push the boundaries for the type of questions we can now ask from the archaeological record.

Genomics: Ancient

MERADETH H. SNOW

University of Montana, USA

The study of genetic material from archaeological contexts is a relatively recent field; however, our ability to illuminate the past in a variety of new and interesting ways has made genomics a dynamic component of archaeological science. During the past 30+ years of ancient DNA (aDNA) study, technological advancements have allowed researchers to go from merely identifying the presence of DNA and RNA, to being able to characterize the entire genome of past humans and hominins. The genome is the complete genetic code found in the cells of an individual, organized into long strands known as chromosomes. Genomics is defined as the field of study in which we look at the whole genome of an organism, rather than individual loci or genes. Growing out of the fluorescence in related fields such as biology and chemistry, genomics has seen significant advances and foibles, but recently has allowed for a variety of insights into the genetic history of archaeological material that would have been impossible only a few years ago.

After death, the mechanisms that control DNA repair in cells cease to function, leading to a variety of breakdowns in the strands of base pairs that comprise our chromosomes and mitogenome (the small, circular piece of DNA housed in the mitochondria of the cell). These nucleotide bases (adenine, cytosine, guanine, and thymine, often abbreviated as A, C, G, and T) form the code that is the genetic basis of our bodies. As DNA decays, the long chains of nucleotides break down into shorter and shorter pieces, often linearly with time. Additionally, the nucleotides themselves can break down, along with a variety of other issues (Fulton 2012). These problems make aDNA difficult to work with, and sometimes even impossible to recover, although many recent advances have aided in making previously impossible samples now viable for analysis. Preservation

of endogenous and accessible aDNA varies widely from site to site, depending on the microenvironment of the soil and conditions of each burial. Typically, higher latitudes and colder environments, with less temperature fluctuation, allow for higher success rates.

Source material

The first studies in the field focused on mummies and other dried tissue (Pääbo 1989); however, it soon became clear that this was a poor source of endogenous DNA because mummified tissues are often contaminated. Skeletal remains are now the most frequently used. Continued research has explored which parts of the skeleton contain the highest amount of endogenous DNA. This has often led to tooth root sampling and, more recently, the drilling of the petrous portion of the skull (Hansen et al. 2017), which appears to carry the highest surviving amount of genetic material.

Ancient DNA has also been recovered from materials such as coprolites (preserved fecal material), quids (chewed plant material), menstrual aprons (LeBlanc et al. 2007), stone tools, and even the very soil in which an individual was buried. Additionally, researchers have used nonhuman sources of genetic material to address questions ranging from human occupation, domestication, and climate change. These novel sources of aDNA will continue to receive attention as researchers look for ways to avoid the destruction of human remains. Moreover, analyses of coprolites and masticated materials allow one to look at the microbiome of the individual—the bacteria inhabiting individuals.

The desire to avoid working with human skeletal material is a growing concern, particularly Native American remains in the United States. While collaboration between geneticists and Native Americans can potentially lead to a better understanding between the two groups (Rasmussen et al. 2015), more needs to be done to help bridge the gap between scientists and Native

communities in order to foster understanding on both sides.

Extraction and analysis

Protocols for DNA extraction vary, but the laboratory itself is a tightly controlled environment. The risk of contamination from modern samples or researchers can be high, as modern DNA can overpower (outcompete) results from that of the sample due to its higher copy number and less damage. These laboratories maintain strict access, cleaning, and other methods that ensure that the amount of contamination introduced to the sample is kept to a minimum. Negative controls are also utilized, allowing for the potential detection of the introduction of foreign DNA to the extraction.

After the aDNA has been extracted from the sample, it can be analyzed in a variety of ways. Some of the original studies used enzyme digests (restriction fragment length polymorphisms (RFLP)), which help to identify notable nucleotide polymorphisms. As methods improved, direct sequencing of the nucleotide bases was carried out, allowing researchers to identify regions of interest within the genome. In particular, single nucleotide bases that differ (single nucleotide polymorphisms (SNPs)) are often focused on to look at individual and population diversity. The advent of next generation sequencing (NGS) has made genomic-level analyses possible. These newer methods, such as the Illumina sequencing platform, have allowed for massive amounts of data to be accrued, permitting whole genomes to be sequenced.

The data that result from NGS platforms are in the form of thousands of short strings of base pairs, known as reads, the length of which varies from less than a hundred base pairs to several hundred. These reads are mixed together and in no particular order, requiring the computational skills often found in the field of bioinformatics. The data are analyzed to remove potentially misread bases or other errors, and also to separate out multiple extractions that were mixed together and can be identified through unique tags added to the DNA through indexing in the preparation process (known as library preparation).

From this, the DNA must be reassembled into the patterns of base pairs that are found in the individual chromosomes or mitogenome of the individual sequenced. This reassembly process is done through software that compares the small fragments of DNA sequence and lines them up against a known, similar sequence. If the species is unrelated to any known comparable species, the *de novo* sequence assembly can still be completed; however, more care must be taken. Due to the data output of NGS, there may be many small DNA fragments that sequence the same base pair locus when all are aligned against one another. This is the concept of coverage, wherein the more times every base pair in the consensus sequence is sequenced, the more confidence one can have in the base being accurate. Should errors or mistakes in sequencing or contamination from an outside source be present in the sample, this would be revealed as a mix of different bases at a locus that are not in agreement. This must be fixed, or taken into account in statistical analyses (such as a low contamination rate being found in ancient genomes). The end result of these analyses is the targeted DNA of interest in the study, which is a long string of base pairs composed of multiple underlying sequence fragments. The more times an individual base pair is sequenced (covered), the stronger the confidence in the data.

Once the genome has been assembled, the type of analysis carried out will vary depending on the study. For example, genomes can identify gene regions, which can aid in understanding variants between individuals and species that may not be captured by looking at only polymorphisms known to exist in one population or species. This ascertainment bias leads to focusing on mutational markers that are found in one group but not necessarily another, which can skew findings as the diversity in one population cannot be captured by the diversity of another.

Applications

The increase in genomic data has led to better understanding the evolution of modern humans. The ability to look at the genome as a whole is beneficial for a variety of reasons, the first being that it allows one to look at a person's maternal

and paternal ancestry bilaterally (and therefore familial relationships). By contrast, uniparental markers (like mtDNA and Y-chromosomes) discern ancestry from only one side. Genomics allows one to document more in-depth relationships between individuals at a single site, and between populations. These can aid in understanding migratory behavior, marriage patterns, and many more anthropologically important topics.

The second large benefit of genomics data is that the data allow for understanding the selective pressures on human populations. These range from the selection for lactose tolerance (Sverrisdóttir et al. 2014), to skin pigmentation (Wilde et al. 2014), disease, and many more. Through specialized analysis, it is possible to see how natural selection, the environment, culture, and other species have all played a role in shaping our genome. The extended benefits of genomics research in archaeology are unfolding, with many more to come.

Ancient DNA has also opened doors into understanding our relationship with other hominin species. Some of the most spectacular results have come in the form of aDNA recovered from remains of *Homo neanderthalensis* and from the remains found at the Denisovan cave in the Altai region of Siberia, Russia. From these findings we can see how we are related to early hominin species, how we interbred with them, as well as selective forces that acted to retain mutations from these other species in our modern human genome.

Many more regional topics have also been investigated through the use of ancient genomics. For example, the peopling of the Americas has long been of interest archaeologically, and through the use of aDNA it has been possible to better understand when and by what route people populated the continents (Bolnick et al. 2016). At a local level, studies within archaeological sites have successfully addressed questions of how individual skeletons were related, such as the identification of maternally related individuals interred in the same room in Chaco Canyon (Kennett et al. 2017).

Human Growth and Development

LUIS RÍOS

National Museum of Natural Sciences, Spain

There is now a well-established scholarship on the bioarchaeology of children, ranging from early works that introduced the osteology of children (Cunningham, Scheuer, and Black 2016), to anatomy manuals for forensic and archaeology practitioners, to volumes devoted to the evolution, biocultural significance, and interpretation of the life and death of subadults in skeletal and living populations (Lewis 2009). A useful theoretical approach to organize the study of subadults is to consider the human life cycle as composed of different bioculturally defined stages (infancy, childhood, juvenility, adolescence, adulthood) (Bogin 1999), through which subadults pass in a process of growth and development. Growth could be defined as a quantitative increase in size or mass (such as the length of long bones), whereas development could be defined as the progression of changes, either quantitative or qualitative, that lead from an undifferentiated or immature state to a highly organized, specialized, and mature state (for instance, dental eruption until functional occlusion for teeth, or size and shape changes of the epiphysis from ossification until fusion with diaphysis) (Bogin 1999). The mature state, or adulthood, would be defined as being a “functionally mature individual.” In other words, the maturity and size of the body, as well as the social engagement and interaction of the person, change along the aforementioned biocultural stages until reaching adulthood (see *BODIES AND EMBODIMENT* and *EMBODIMENT*). The two most basic steps on which subsequent analysis of subadult remains rely are the estimation of sex and age-at-death, placing the individual within one of these developmental stages. Then, the study of growth and maturation presents a broad picture of the living conditions of subadults,

increasing our knowledge of the structure and dynamics of past societies.

Sex estimation and juvenile remains

Research on sex estimation has moved from qualitative assessment of pelvic and cranial traits and classic metric dimensions (permanent canine crown diameter) to 3D analysis of shape (see *IMAGING IN HUMAN REMAINS*), offering some improvements in the understanding of the development of sexual differences in the skeleton. However, due to the fact that most of the skeletal sex differences in adult size and shape develop from the adolescent stage onwards (in parallel to secondary sexual development), no reliable method for the estimation of the sex of subadults based on morphological observations is currently available. The definitive tool for sex determination in younger ages is the genetic analysis (see *CHROMOSOMAL DNA AND GENETICS: ANCIENT*), still of limited use due to its invasive sampling, need of laboratory infrastructure, and cost. The lack of a reasonably accurate, and straightforwardly applicable, method for sex estimation of subadult remains results in an important loss of information for the biocultural reconstruction of the lives of, at least, preadolescents.

Juvenile age-at-death estimation: biological and chronological age, and within-population variation

In the estimation of the age-at-death of subadult remains, it is first important to understand the difference between biological age and chronological age. Biological age (BA) estimation was originally devised for comparison with chronological age (CA) in pediatric studies, in order to ascertain the degree of delay or advance in maturation of a particular child in comparison with reference data for healthy children, and not for pinpointing CA (Cameron and Bogin 2012). The basic assumption of the methods available to assess BA is that

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0308

for living, healthy human children, juveniles, and adolescents, CA and BA are highly correlated and one year of CA advancement will equal one year of BA advancement. It is also important to note the normal within-population variation in the relation between BA and CA, which can be considered as a measure of the biological resolution of these methods. As recently stated, “Invariably the spread of actual ages around any particular maturity indicator and/or the spread of maturational ‘ages’ around any particular chronological age are of the order of ± 2 years” (Cameron 2015). When an age-at-death is estimated for a subadult skeleton, we are currently extrapolating a CA from a BA. There are three broad categories of BA, namely dental, skeletal, and somatic, whose use in age-at-death or CA estimation of subadult remains is reviewed here.

The most widely used method for CA estimation of subadult remains is the estimation of dental age, based on the simultaneous assessment of tooth formation and eruption in the so-called dental charts, the Schour and Massler, Ubelaker and London atlases being the most commonly used (Cunningham et al. 2016) (see ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION). This qualitative approach can be complemented by the metric study of developing teeth.

The assessment of skeletal age can also be used for CA estimation, mainly in terms of degree of fusion between ossification centers (see ESTIMATING SUBADULT AGE: EPIPHYSEAL UNION). One of the problems of this approach is the scarcity of accurately known sex and age skeletal collections of subadults (the most widely known being Lisboa and Coimbra in Portugal, Granada in Spain, Spitalfields and St Bride’s Church in the United Kingdom, Bologna in Italy, Haman-Todd in the United States, and Dart in South Africa), with limited sample sizes especially from two to three years onwards. Small sample sizes result in a limited knowledge of the normal variation in bone maturation, although the above-mentioned interval of ± 2 years of variation between BA and CA for the most used pediatric methods should be always considered. Further complications when using subadult documented collections come from differences in bone maturation between populations (addressed below), and from the representativeness of the

growth and maturation of these children in relation to the population at large (the survivors). The solution has been to combine data from different documented collections and increasingly study clinical data (radiographs, computed tomography (CT) scans, and magnetic resonance imaging (MRI)), a strategy that allows one to gather large, and sex-balanced, sample sizes. Results are already available for CA estimation from skeletal maturation of living samples, several of them including Bayesian statistical approaches (see BAYESIAN STATISTICS AND ESTIMATING ADULT AGE: TRANSITION ANALYSIS) (Lottering et al. 2016).

Finally, CA can be estimated from a measure of size attained, through dimensions of different bones (see ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH), from dozens of measurements from the prenatal to early postnatal periods, to selected dimensions (generally lengths and widths) of cranial and postcranial bones for later ages. The most used measurements are long bone lengths and widths, and there are recent summaries of formulae for age estimation (Cardoso, Vandergugten, and Humphrey 2016). However, as mentioned for bone maturation, it is important to note that there might be major differences in growth between populations that limit estimation of CA from size, which are addressed in the next section.

Growth and maturation assessment and between-population variation

When we estimate age-at-death we are thus extrapolating a CA from a BA, and the normal ± 2 years within population variation should always be acknowledged. However, there is also considerable variation between populations in growth and maturation due to socioeconomically mediated differences in the quality of the environment during the subadult period (nutrition, disease, workload). Intergenerational changes towards earlier teeth formation have been observed in some populations in parallel to modernization, although other authors found no delay in tooth formation associated with sustained malnutrition, and the general consensus is that teeth present substantial biological stability to environmental insults.

Accordingly, dental age assessment is the most robust method for CA estimation. Delays in skeletal maturation have been observed associated with adverse environmental conditions, and intergenerational changes towards earlier bone maturation have been observed parallel to improved living conditions (Cameron and Bogin 2012). Finally, height-for-age (or its skeletal proxy like femoral length) is generally used as an anthropometric measure for assessment of growth status in living children (Cameron and Bogin 2012), and several studies of positive and negative temporal changes in adult stature across generations have been observed parallel to political, social, and economic changes in diverse human populations (Bogin 1999). A recent comprehensive study of a Neandertal juvenile skeleton illustrates the importance of considering all these biological and environmental factors when studying growth and maturation (Rosas et al. 2017).

A critical step in the estimation of CA from BA in subadult remains is thus the choice of the method in terms of the differences between the subadult sample under study and the child sample from which the method was developed. If our study sample and the reference sample differ significantly in the quality of the environment during the growth period, it is likely that we will under- or overestimate CA from BA, since we would be incorporating in our CA estimation the between-population variation in both samples. If we use modern references developed in middle-class to well-off samples of children, then the most probable risk is that of underestimation of CA (Lampl and Johnston 1996). This risk can be diminished when the reference sample comes from the aforementioned documented collections, since most of them come from populations of children living in unfavorable conditions which could more likely resemble that of past populations. For CA estimation, especially when using size measurements, the best procedure would be to have population-specific references, or to choose a reference sample known to show similar growth conditions to the sample under study.

In fact, taking into account the sensitivity of skeletal maturation and growth to the quality of the environment, the general strategy in bioarchaeological studies is to use dental age as the

closest estimate of CA, and then look for differences in skeletal maturation and size in relation to a modern reference as a measure of the quality of the environment of growth. This approach can be further refined by the differential growth and maturation of different skeletal systems across the stages of the life cycle, with the implication that a record of the environment during different stages is archived in different parts of the skeleton. The classical example of analysis of different teeth and/or of sections within a single tooth to obtain a chronological record of different periods of the life of the individual in terms of diet and mobility (see DIET AND CARBON ISOTOPES; DIET AND NITROGEN ISOTOPES; DIET AND SULFUR ISOTOPES; DIET AND TRACE ELEMENTS; and INFANT FEEDING) can also be expanded to growth and maturation of the skeleton. For instance, the well-known early growth and maturation of the bones associated with the central nervous system would record environmental insults during the early stages of the life cycle, while the estimation of age of initiation and completion of the adolescent growth spurt could be associated with the quality of the environment during late juvenility and the adolescence period. In this regard, a very interesting addition to the classic works on childhood is the recent research addressing the estimation of puberty in skeletal remains (Lewis 2016).

The estimation of age-at-death and the outlined biocultural approach for basic growth and maturation assessment in subadult remains constitute the basis for further dental and skeletal research. For instance, the study of pathological conditions (see PALEOPATHOLOGY) in subadult remains is an increasingly important area of research, with recent interesting contributions from trauma, and metabolic and infectious diseases (see Lewis 2018). It is only through the joint consideration of all the available osteological, archaeological, and documentary information (see BIOARCHAEOLOGY) that the full potential of subadult skeletal remains for bioarchaeology can be realized.

Human Skeletal Geochemistry

KRISTIN K. HOFFMEISTER and LORI E. WRIGHT

Texas A&M University, USA

The field of geochemistry examines the chemical composition of the soils, rocks, and oceans of the Earth to understand the processes by which our planet was formed and has been transformed through the ages. As such, geochemists use the methods of chemical analysis to identify the physical and chemical processes that led to the formation and distribution of natural materials. The geochemical analysis of bone emerged following the discovery of radiocarbon dating, now often applied to archaeological bone. After death, the remains of all living things, including humans, enter the geological arena. The human skeleton contains a mineral structure that is part of this arena, both before and after death. Geochemical principles can be applied to understand how bone forms, its natural composition during life, and how bone undergoes changes in chemical composition after its entry into a burial context. Human behavior determines the chemicals that ultimately enter the body, and therefore, the bones. Accordingly, the chemistry of archaeological human bones can shed light on environmental, cultural, chronological, and biological aspects of past human lives.

Bone microstructure

Bone comprises both organic and inorganic components, which account for roughly 30 percent and 70 percent of the total dry weight of bone, respectively. The organic component of bone is primarily formed from type I collagen, a protein that forms the structure of many bodily tissues, including tendons, ligaments, skin, and bone. While collagen comprises roughly 90 percent of

the organic component of bone, the remainder is made up of noncollagenous proteins, lipids, and water. The isotopic composition of collagen has been used to reconstruct paleodiet via stable carbon (see DIET AND CARBON ISOTOPES), nitrogen (see DIET AND NITROGEN ISOTOPES), and sulfur (see DIET AND SULFUR ISOTOPES) isotopes, which broadly reflect the protein-based components of diet (Ambrose and Norr 1993). In addition, isotopes of carbon are used to radiocarbon date materials. Amino acid racemization is also used to date archaeological deposits.

In contrast, the inorganic component of bone is composed of mineral crystals of a calcium phosphate called hydroxyapatite, or hydroxylapatite. Hydroxyapatite is a carbonated apatite that is usually written as $\text{Ca}_{10}(\text{PO}_4)_6\text{OH}_2$. While hydroxyapatite has a defined chemical composition, it can be variable depending on interactions with other elements. Hydroxyapatite, like other members of the apatite group, has several sites where atomic exchanges can occur. Atomic exchanges of this kind occur when ions of similar size and charge substitute for one another in the hydroxyapatite crystal lattice. Most significantly, skeletal hydroxyapatite is carbonated, meaning that carbonate ions substitute for the phosphate group (Type B substitution) and to a lesser degree at the hydroxyl positions (Type A substitution), and adhere to the surface of the thin plate-like or book-like hydroxyapatite crystals (Le Geros 1981). Researchers have investigated paleodiet and paleomobility via trace element analysis (see DIET AND TRACE ELEMENTS), as well as carbon (see DIET AND CARBON ISOTOPES), oxygen (see MOBILITY AND OXYGEN ISOTOPES), calcium, lead (see MOBILITY AND LEAD ISOTOPES), and strontium (see MOBILITY AND STRONTIUM ISOTOPES) stable isotopic compositions of hydroxyapatite.

Alkaline earth elements in bone

Substantial geochemical research has focused on elements that can substitute for calcium and

phosphorus in hydroxyapatite. Calcium (Ca), strontium (Sr), and barium (Ba) are all alkaline earth elements, which are those elements in the second column of the periodic table that share structural and chemical similarities. In the case of strontium and barium, both are positively charged, divalent atoms that are similarly sized to calcium, which allows them to replace calcium in hydroxyapatite. Sr and Ba are not metabolically regulated; instead, their levels in bone broadly reflect their abundance in the diet. Thus, researchers have used the ratios of Ba/Ca and Sr/Ca in bone to reconstruct paleodietary behavior, as well as Ba/Sr ratios to detect consumption of marine resources (Burton and Price 1990).

Strontium and barium atoms are slightly larger than calcium. In the body, this means that Ba and Sr are not incorporated into hydroxyapatite at the same rate as calcium. This process, wherein calcium is preferentially absorbed relative to strontium and barium, is called biopurification. The net result of biopurification is that the amount of barium and strontium in hydroxyapatite is less than the levels of either in the diet, such that there is a trophic level effect moving up the food web (Burton, Price, and Middleton 1999).

A variety of factors limit the analytical potential of using strontium and barium levels in bone to reconstruct paleodiet (see DIET AND TRACE ELEMENTS). There is substantial variation in both barium and strontium levels across space such that geographical differences could mask any dietary differences (Burton et al. 2003). Furthermore, the barium and strontium abundances in bone are not directly proportional to diet; instead bone Ba/Ca and Sr/Ca are disproportionately influenced by foods high in calcium (Burton et al. 1999).

Non-alkaline earth elements in bone

Although lead (Pb) is not an alkaline earth, it substitutes for calcium in hydroxyapatite in much the same way as barium and strontium, and isotopic studies have investigated mobility patterns using lead isotopes in bone (see MOBILITY AND LEAD ISOTOPES). Zinc (Zn) also occurs in bone and has received some attention in paleodietary

studies, although it does not appear to reliably reflect dietary behavior (Dolphin and Goodman 2009).

While many elements are incorporated into bone via biogenic processes, multi-element assays may also help to identify postmortem elemental exchange, or diagenesis (see DIAGENESIS OF BONE). Once deposited in an archaeological context, bone mineral interacts with the burial environment. These changes can be classified as either diagenesis or contamination. Changes to the chemical structure of the bone, involving additions to the crystal structure, loss of elements due to leaching, and substitutions of ions that occur postmortem, constitute diagenetic changes. In addition, bone may become contaminated by exogenous materials. Such contamination may consist of deposition or recrystallization of exogenous minerals within the normal spaces in the bone architecture. Deterioration of the organic collagen architecture of the bone provides a further context for mineral exchange, speeding the process of diagenetic exchange. Diagenesis and contamination are concerns for both trace element and stable isotope analyses. Since highly carbonated hydroxyapatite is quite soluble (Le Geros 1981), efforts to minimize both contamination and diagenesis have emphasized the dissolution of surface mineral with a buffered, dilute acetic acid (Crowley and Wheatley 2014).

Early research in bone chemistry attempted to examine exchange between bone and the burial context by searching for patterning between bone and adjacent soil, with variable success (Lambert et al. 1984). Screening methods to identify bones with higher levels than expected of nonbiological contaminants have been more useful. For instance, iron, aluminum, potassium, and rare earth elements are not found in appreciable levels in bone, and when found, they signal contamination from soil or the burial environment. High barium levels may indicate the crystallization of barite (barium sulfate) in bone lacunae, while microbial action may deposit magnesium oxides on bone in the burial context. Therefore, multi-element studies of bone mineral can identify elevated Sr or Ba levels that should be ascribed to diagenesis rather than diet (Price 1989). Examining the chemical composition of bone can be done via different analytical

instruments, including atomic absorption spectroscopy, particle induced X-ray emission (see ION BEAM ANALYSIS (PIXE/RBS) and PIXE AND MATERIAL ANALYSIS), mass spectrometry (see MASS SPECTROMETRY (MS)), X-ray fluorescence spectroscopy (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), inductively coupled plasma mass spectrometry (see ICP-MS AND MATERIAL ANALYSIS), and neutron activation analysis (see NEUTRON ACTIVATION ANALYSIS (NAA)). Stable isotope ratios are measured by mass spectrometry or thermal ionization mass spectrometry. Data collected following laser ablation can allow smaller sample sizes for some of these modalities.

Imaging in Human Remains

PATRICK EPPENBERGER and FRANK RÜHLI
University of Zurich, Switzerland

Background and development

Paleoradiology can be defined as the use of medical imaging techniques such as conventional X-ray imaging, X-ray computed tomography (CT), X-ray microtomography or computed microtomography (micro-CT) and magnetic resonance imaging (MRI) for the study of bioarchaeological materials.

In the first two decades after the discovery of X-rays by Wilhelm Conrad Roentgen (1845–1923) in November 1895, radiological studies were conducted by scientists from various backgrounds, including photographers, chemists, physicists, and physicians. Indeed, from its early beginnings, the discipline of paleoradiology arose in parallel with the development of radiology and medical imaging technology.

Since Roentgen had waived any patent protection of his discovery and published it in an “open source” manner, knowledge about his experimental setup swiftly spread around the world (Roentgen 1959). In March 1896, only a few months after Roentgen first published his discovery, the physicist Walter Koenig (1859–1936) published the first radiographic image of a bandaged ancient Egyptian child mummy from the Senckenberg Museum of Natural History, Germany (Koenig and Barth 1896). The plain anteroposterior X-ray image of this mummy’s knee region was the very first of its kind. It is of astonishing quality even by modern standards. The radiographic equipment of the time was mobile and was used on site, but required a long exposure time, of several minutes. In the following years, further researchers, primarily in Europe and in the United States, performed similar radiological investigations of ancient human remains (Boni, Ruhli, and Chhem 2004). The

most common countries of origin of mummies investigated at the beginning of the twentieth century were Egypt and Peru. For example, in 1904 the anatomist and anthropologist Sir Grafton Elliot Smith (1871–1937), assisted by Howard Carter (1874–1939), was able to determine the age at death of King Tutmosis IV through an X-ray examination of his mummy (Smith 1912). The term *paleoradiology*, however, was introduced much later, by Derek Notman and his colleagues in 1987, after an examination of the frozen bodies of three British sailors, members of the ill-fated 1846 Franklin expedition to the Northwest Passage in the Canadian arctic (Notman et al. 1987).

In current clinical practice the established imaging techniques (conventional X-ray, CT, and MRI) are widely used to diagnose diseases. Paleoradiological imaging is nowadays applied in a similar manner, in order to detect and describe pathologies and variations in normal anatomy. The purpose of the very early X-ray studies often was, on the contrary, simply to distinguish authentic mummies from replicas and to search for burial goods. Subsequently the identification of skeletal diseases or the evaluation of bone age became the focus of attention.

With the introduction of CT in the early 1970s, the application of paleoradiology expanded substantially; noninvasive analyses of body cavities were now possible. Godfrey Hounsfield (1919–2004) and Allan M. Cormack (1924–98) independently described this X-ray-based cross-sectional imaging technique, for which they were awarded the 1979 Nobel Prize in Physiology and Medicine. In 1976 Lewin and Harwood-Nash performed the first CT examination of mummified tissue from ancient Egypt. They imaged the desiccated brain of Nakht, the mummy of an adolescent male from the twenty-first dynasty, as well as the complete body of Djedmaatesankh, the mummy of an adult female from the twenty-second dynasty, both from the collection of the Royal Ontario Museum (Harwood-Nash 1979). In mummy research nowadays CT imaging is commonly used to non-invasively examine a range of parameters such as

bone and soft tissue preservation, postmortem damages, mummification and embalming techniques, sex, pathologies, traumata, traces of medical interventions, age at death, possible causes of death, and even artificial cranial deformation.

Micro-CT was later developed to improve CT image resolution. It is mostly used in scientific applications rather than in clinical imaging, since only small samples—a few centimeters in diameter—can be scanned. Micro-CT can be used to study ancient teeth or to investigate mummified materials and fossils, since it provides an excellent depiction of anatomical details at submillimeter resolution.

In the late 1970s, a team led by John Mallard built the first full body MRI scanner at the University of Aberdeen; and in 1980 the first clinical MR images of a patient were acquired using this machine (Mallard et al. 1979). However, for over two decades, MRI has not been considered suitable for paleoradiological studies, since the MRI signal generally originates from free water in the imaged tissue, which is not present in desiccated ancient human remains. In an extreme attempt, even rehydration of desiccated ancient human tissue was tried, which obviously led to the loss of the specimen (Shin et al. 2010). Novel MRI techniques can now detect remaining bound tissue water in desiccated bioarcheological samples and permit nondestructive acquisition of high-quality MR images. Their common key element is the ability to compensate for the rapid MR signal decay in bound tissue water, for example by using ultrashort echo time sequences (UTE).

Indications and implications

The application of standard medical imaging techniques in bioarcheological investigations can serve many purposes and requires a distinctive methodology. Unfortunately the use of imaging technology is often limited by multiple factors, such as the availability and portability of the imaging equipment, financial costs, and challenges related to obtaining permission to move or transport ancient specimens for examination.

Thus conventional (digital) X-ray remains the primary modality for paleoradiological imaging. Portable digital imaging units can even be used for examinations at excavation sites or in museums. Most importantly, conventional X-ray also provides higher spatial resolution than CT or MRI (See Figure 1a and b). Despite of the wider availability of CT and MRI, or even of micro-CT, these modalities still serve mostly to clarify findings already seen on conventional X-ray images.

The focus of paleopathological studies is on the identification of pathologies and variations in normal anatomy, and the list of radiologically documented pathologies in ancient human remains essentially covers all major groups of pathologies known today.

An understanding of the characteristics of bioarcheological materials and postmortem changes is essential to establishing a careful differential diagnosis of paleoradiological findings. Dry-bone specimens or mummified remains show substantial variations in composition. In general they are dense, owing to the loss of water, and this makes it difficult to distinguish between different types of tissue. In addition, infiltrates from the surrounding soil may mimic sclerotic areas, while bone degradation due to acidic soil conditions can easily be mistaken for osteolytic processes. Substances employed during a mummification or embalming process or added later, during museum curation, will also alter a tissue's radiological appearance. Skeletal alterations typically associated with traumatic or rheumatologic diseases are the most frequent findings; but tumors have also been described in various studies. However, many skeletal lesions share common, nonspecific radiological characteristics, while pathognomonic patterns are rather rare and only apply to a few skeletal lesions such as fracture, nonossifying fibroma, and osteochondroma. The time of occurrence (peri- vs. postmortem) of a specific trauma is difficult to assess radiologically, unless signs of bone remodeling are present. Besides pathologies in hard tissues, disorders in soft tissues can also be identified. Mummies of different origins often have well identifiable cardiovascular structures where calcifications can frequently be found as evidence of atherosclerosis. X-ray images or CT scans also permit measurement of anatomical structures, which is taken in

order to determine the stature, the age at death, and the sex of an individual (e.g., of a wrapped mummy) for paleoanthropological studies.

Indeed, CT has even been used to identify skeletal remains embedded in a soil matrix, without destruction of the fragile specimens (Chhem, Brothwell, and SpringerLink 2008). Such specimens may also contain materials of high density and atomic number, such as funerary accessories, jewelry, tools, weapons, or body adornments. On the other hand, the bioarcheological material can itself be contained in a stone or ceramic vessel;

for example, mummified organs can be found in Egyptian Canopic jars (Figure 1c).

Concerns about the use of ionizing radiation when ancient human remains are imaged are legitimate, since such specimens are unique and irreplaceable. However, ionizing radiation from natural sources (like cosmic radiation and radon gas) has constantly affected any ancient specimen over time, thus in theory resulting in an integrated dose two, three, or even four magnitudes higher than the dose applied for an X-ray or CT examination.

Further techniques and future directions

Throughout its history, paleoradiology has benefitted from close interdisciplinary collaboration between radiologists, paleopathologists, and bioarcheologists, as well as other basic scientists. To achieve an improved differentiation of historical mummified tissue, various new methods based on CT, MRI, and even terahertz (THz) imaging have recently been applied in interdisciplinary research projects.

As mentioned, standard MR-imaging of dry tissue is generally limited by the low content of protons in the material. Newly developed, mostly UTE-based, MRI sequences for ancient remains are likely to provide images with significantly improved contrast and resolution, possibly surpassing X-ray-based imaging technologies in the future. MRI of other nuclei than hydrogen (^1H), such as sodium (^{23}Na) or carbon (^{13}C), is another promising technique, especially for the examination of Egyptian mummies, since Egyptian embalmers used natron, a mixture of sodium carbonate and sodium bicarbonate, for mummification.

A more recent development in CT scanning is known as dual-energy computed tomography (DECT). By using two different tube potentials, two CT datasets can be acquired with different X-ray spectra. The additionally obtained spectral information can then be exploited to identify elements of different atomic number. This can be particularly helpful in the analysis of mummified remains, as they often contain many types of materials (bone, cartilage, soft tissues, hair, embalming materials, textiles, wood, or even metal parts).

THz imaging is of particular interest, since it is a noninvasive and nonionizing diagnostic modality. While clinical imaging applications in the THz frequency range (100 GHz–5 THz) are quite limited by the strong absorbing properties of water, the low water content of most bioarcheological materials facilitates THz investigations. However, due to the greater wavelengths, THz radiation will always provide lower spatial resolution than X-ray based imaging or MRI. Nevertheless it has potential, for example in the recognition of hidden objects in historic samples, or in the

identification of specific spectral signatures from chemical substances used for embalming.

Such techniques, novel to the field of paleoradiology, are now increasingly used to expand diagnostic capabilities in unique human tissue samples. But advances are also being made in the way imaging data can be further processed. 3D printing techniques allow multiple copies and hands-on access to specimens without damaging or even touching the original.

Paleoradiology will inherently remain an experimental discipline, where each method offers its benefits and limitations. The decision about the best approach will thus continue to benefit from close interdisciplinary collaboration between scientists from different disciplines.

Infant Feeding

TRACY L. PROWSE

McMaster University, Canada

The study of infant and young child feeding in past populations is an active area of research because early diet, nutrition, and health are key determinants of childhood survival and adult health. The duration of breastfeeding can ultimately influence the demographic profile of a population because breastfeeding can suppress ovulation and increase interbirth intervals. The term “infant” usually refers to individuals under one year of age, so when discussing infant and young child feeding, this covers the period from birth through the completion of weaning and the shift to a post-weaning diet. There is a general human pattern of exclusive breastfeeding to six months of age, followed by the weaning process that is characterized by an extended period of transitional feeding with complementary foods (Sellen 2007). Exclusive breastfeeding provides energy and nutrients to the growing infant and also protects against infections and disease through passive immunity provided by maternal breast milk. The duration of breastfeeding is critical for the survival of the infant; too little breastfeeding can lead to high rates of infant morbidity and mortality, whereas extended exclusive breastfeeding beyond six months of age may not provide the necessary energy and nutrient requirements for normal growth and development. This is known as the “weanling’s dilemma,” that is, the balance between the nutritional and energy requirements of growing infants and their immunological development. Despite a general life-history pattern of infant feeding in human populations, there is considerable variability in the timing and duration of breastfeeding related to both individual choice and broader cultural attitudes and norms. Of interest to researchers studying archaeological populations are the social, political, and economic factors that

may have impacted breastfeeding and weaning practices.

Weaning is a process characterized by the gradual removal of breast milk and the introduction of complementary foods, and it ends with the complete cessation of breastfeeding. Prior to the use of biochemical techniques to investigate patterns of infant and young child feeding in past populations, weaning was often inferred from osteological indicators of stress (e.g., enamel hypoplasias, Harris lines, cribra orbitalia, and porotic hyperostosis), because these indicators were thought to be related to weaning stress. This is because during the weaning process, infants come into contact with pathogens present in complementary foods and water, and have greater interactions with their environment, putting them at greater risk for illness and death. There are, however, problems with using these osteological indicators to infer infant and young child feeding, not the least of which is that they can be caused by a variety of stressors including diet, disease, and trauma.

Elemental studies of breastfeeding and weaning in archaeological contexts have analyzed strontium (Sr) to calcium (Ca) ratios in bone, because Sr/Ca ratios are lower in infants who exclusively breastfeed (Sellen and Smith 1984). There is also potential in the study of barium (Ba) to Ca ratios in relation to breastfeeding and weaning, as Ba/Ca ratios are higher in breastfeeding infants, but this has not been widely used in bioarchaeological studies. Concerns over the relationship of trace element data to diet and diagenetic effects on trace element values in buried bone have limited the use of Sr/Ca ratios to study weaning patterns, although the use of tooth enamel is promising, as it is more resistant to diagenesis.

The stable isotopes of nitrogen ($\delta^{15}\text{N}$) and carbon ($\delta^{13}\text{C}$) in bone collagen are most often used in biochemical studies of breastfeeding and weaning, although oxygen ($\delta^{18}\text{O}$) isotopes have also been employed. Nitrogen isotopes are regularly used in weaning studies based on the “trophic-level effect,” in which the $\delta^{15}\text{N}$ tissue

values of consumers are higher than those of the foods consumed (by 2–4‰) (per mil), although the magnitude of this difference varies between species. Studies of modern mother–infant pairs demonstrated that the $\delta^{15}\text{N}$ values in the finger-nails and hair of exclusively breastfeeding infants were higher than those of their mothers (by 2–3‰) and there was also a similar, but smaller (1‰), trophic-level shift in $\delta^{13}\text{C}$ values (Fogel, Tuross, and Owsley 1989; Fuller et al. 2006). Once the weaning process starts and breast milk is removed from the diet, $\delta^{15}\text{N}$ values decrease to reflect the removal of breast milk. A sharp decrease in $\delta^{15}\text{N}$ between age groups is interpreted as the rapid removal of breast milk from the diet, whereas a gradual decrease is interpreted as a more drawn-out weaning process. There are, however, a number of underlying assumptions implicit in the use of $\delta^{15}\text{N}$ data in weaning studies, such as: the adult female $\delta^{15}\text{N}$ mean is equal to that of the mothers who provided milk, there is little variability in adult female diet, diet-to-tissue offsets in $\delta^{15}\text{N}$ values are the same in both adults and infants, and the weaning trajectories of young children are identical (Reynard and Tuross 2015). An additional complicating issue is that $\delta^{15}\text{N}$ values in infant bones can be influenced by factors such as maternal diet, stress during fetal development, stress associated with malnutrition or disease in the infant, and the physiological demands of growth, all of which can variably impact $\delta^{15}\text{N}$ values.

Carbon isotope ratios are not typically used on their own to track breastfeeding and weaning due to the smaller trophic-level effect, but $\delta^{13}\text{C}$ values are used in concert with $\delta^{15}\text{N}$ data to detect the introduction of complementary foods. The analysis of $\delta^{13}\text{C}$ data can be used to infer the use of C^4 -based weaning foods, such as millet or maize, or the early introduction of marine foods in the weanling diet, all of which result in higher $\delta^{13}\text{C}$ values. Oxygen isotopes ($\delta^{18}\text{O}$) are used to investigate geographic origins and mobility in past human populations (see MOBILITY AND OXYGEN ISOTOPES), because the oxygen in local precipitation largely determines $\delta^{18}\text{O}$ values in human tissues, and varies in relation to latitude, elevation, temperature, humidity, and distance from water. The $\delta^{18}\text{O}$ signals of exclusively breastfeeding infants are higher than adult female values (by $\sim 2\text{‰}$), because human breast

milk is produced from available body water that is enriched in ^{18}O over the water consumed by the mother. Oxygen isotope values are usually obtained from tooth enamel, so the isotopic analysis of permanent teeth formed at different periods during infancy and childhood can be analyzed, and lower $\delta^{18}\text{O}$ values in progressively later forming teeth are used to infer that weaning occurred (Wright and Schwarcz 1998). $\delta^{18}\text{O}$ values in bone can also be used to investigate breastfeeding and weaning patterns, but it is necessary to consider variability in bulk bone $\delta^{18}\text{O}$ values associated with seasonal variation in climate, mobility, and seasons of birth and death.

Stable isotope data are usually obtained from bone collagen samples, which reflect the protein composition of the diet, and information on total diet is derived from bone apatite (the inorganic portion of bone). One issue with using bone is that it has a relatively slower turnover time than other body tissues like hair and nails, so there is a lag time between changes in diet and a record of this shift in bone. This lag time is estimated to take weeks to a few months, depending on the rate of bone formation and turnover, which is not well understood. In an effort to contend with the issue of lag time in bones and to develop a more precise estimate of the timing and duration of breastfeeding and weaning, Tsutaya and Yoneda (2013) employ mathematical modeling to estimate the initiation and duration of the weaning process.

A confounding issue in studying infant and young child feeding in past human populations is that the data are derived from mortality samples, that is, from those individuals who did not survive infancy and childhood. In order to reconstruct breastfeeding and weaning patterns, the sample is necessarily cross-sectional (i.e., bones are sampled from deceased individuals in each age category). Thus, we do not know if these nonsurvivors were breastfed and weaned in the same manner as survivors. In order to contend with some of the issues associated with using bone of nonsurvivors for isotopic analyses, sequential samples of tooth enamel and dentine are now a focus of study. These tissues form during infancy through adolescence and remain relatively unchanged throughout life, so the sequential analysis of permanent teeth means that isotope data about breastfeeding

and weaning are obtained from individuals who survived childhood, minimizing the issue of mortality bias in stable isotope studies. Sequential samples from teeth can track intra-individual (i.e., longitudinal) dietary variation and result in more precise estimates of the timing of breastfeeding and weaning, because the stages of tooth development are well known. Advances in microsampling of teeth and developments in mass spectrometry mean that smaller sample sizes can be used for isotopic analysis and greater temporal resolution can be obtained (Henderson, Lee-Thorp, and Loe 2014). One problem is that enamel and dentine do not grow in horizontal layers, so serial sections taken from teeth (usually done horizontally) may represent overlapping periods.

It is important to recognize the underlying assumptions and limits of stable isotope analyses, particularly with respect to data derived from the bones of nonsurvivors. New methods of isotope analysis are enhancing our understanding of infant and young child diet in the past, and offer greater precision in the estimation of when this important first dietary transition occurred in past populations.

Infectious Disease

MOLLY K. ZUCKERMAN
Mississippi State University, USA

Much of the study of infectious or contagious diseases within the archaeological record has occurred within the fields of paleopathology (see PALEOPATHOLOGY), the study of ancient disease, and paleoepidemiology, the study of population-level disease dynamics within past populations. However, an increasing body of work on the issue has recently emerged from biomolecular research: ancient DNA studies (aDNA) (see GENETICS: ANCIENT), archaeogenetics, the application of population genetics to the study of past populations, and ancient pathogen genomics, the study of ancient pathogen genomes (see GENOMICS: ANCIENT), as well as related fields. Motivations for these inquiries have shifted throughout time. Infectious disease, particularly treponemal disease (i.e., syphilis, yaws, bejel), was a major focus of paleopathological inquiry in the late nineteenth to early twentieth century, soon after the field's late-eighteenth-century emergence. These works took the form of case studies and were focused on the individual case studies of single disease episodes and documentation of the presence of different types of infectious diseases across cultural and temporal contexts. With the inception of paleoepidemiological research in the 1960s and 1970s, analyses of infectious disease in the archaeological record have increasingly shifted towards population-level analyses of the ecology and evolution of infectious diseases and of interactions between pathogens and their human hosts. Augmented and enabled by innovations in biomolecular research since the 1990s and early 2000s, contemporary research on infectious disease within the archaeological record is largely oriented towards characterizing coevolutionary relationships between human hosts and their pathogens and interactions between humans, pathogens, and their environments. Within this, analyses frequently focus

on how these dynamics have impacted human evolution, especially susceptibility to disease, and pathogenic evolutionary responses to biological, economic, social, and technological changes within human societies over time.

Issues impacting the study of infectious disease in the archaeological record

Several material issues impact the study of infectious disease in the archaeological record. Some of these have been largely resolved recently, but others are characteristic of archaeological human skeletal material, or are unique to the study of disease in the past and therefore persist. Material limitations that are fundamental to archaeological research include small sample sizes and the frequently poor preservation and incompleteness of archaeological material, including skeletal material. More unique to the study of disease is the issue that few diseases, including infectious diseases, affect the skeleton, and those that do are typically chronic (versus acute) in course. This limits the archaeological visibility of many diseases. Up until recent innovations in biomolecular research, this effectively limited inquiry to a relatively short list of chronic infectious conditions. These included some macroparasitic organisms, such as intestinal worms, as well as microparasitic diseases such as tuberculosis, leprosy, and treponemal disease. Another issue is that the skeleton can only physiologically respond to insult in a limited way, which means that different diseases can produce highly similar manifestations. Only a few diseases produce highly specific, diagnostic lesions. This means that many diseases, including infectious diseases, cannot be macroscopically or grossly identified in skeletal material with a great degree of accuracy. Whether infected individuals manifest skeletal lesions is further moderated by host resistance factors, namely age, sex, health status, and immunological competence. Viewed within a biocultural model, these factors are both produced and influenced by environmental constraints and conditions.

Communities can strategically buffer themselves against their environments through technologies, social organizations, and ideologies. This can reduce individual-level vulnerability to infection, risk of additional infection (co-infection), and associated morbidity and mortality. However, in socially stratified societies, these strategies can buffer privileged individuals while exacerbating stressors and their effects for the disadvantaged, increasing their vulnerability to infectious disease. Some cultural practices can also act as stressors, such as the use of irrigation agriculture and the associated rise of water-based infectious diseases, such as schistosomiasis, an acute and chronic disease caused by parasitic worms.

Several methodological and theoretical issues also impact the study of infectious disease within the archaeological record. One methodological issue is that the popularity of case studies prior to the 1960s and 1970s greatly limited population-level analyses of the evolution, coevolution, and ecology of diseases within past human populations. Another is that evidence-based, standardized diagnostic criteria that incorporate concepts from differential diagnosis in clinical medicine and disease screening within epidemiology exist for only a small number of infectious conditions that affect the skeleton. These include treponemal disease, malaria, and leprosy (see DIFFERENTIAL DIAGNOSIS). Infectious diseases that do not produce clear diagnostic skeletal changes cannot be diagnosed with nearly the same accuracy. Many researchers also do not use the same set of diagnostic criteria, which reduces the comparability of various studies and their results (Zuckerman, Harper, and Armelagos 2016).

The osteological paradox

Several theoretical issues are fundamental to archaeological research, such as the time frame(s) represented by archaeological assemblages (time averaging), selection biases that arrive from mortuary and related practices (see MORTUARY ANALYSIS), and issues of the representativeness of a given archaeological sample. Two additional factors, which are key components of the osteological paradox, further impact the issue of sample representativeness in research reconstructing past health and disease (Wood et al.

1992). These are hidden heterogeneity in frailty and selective mortality (see PALEODEMOGRAPHY AND HAZARDS ANALYSIS). Hidden heterogeneity in frailty comprises individual-level variation in host resistance factors and consequently susceptibility to different diseases, as well as individual experiences of stress and risks of death. Selective mortality, which acts upon heterogeneity in frailty, means that skeletal samples composed of individuals with high age-specific frailty are therefore not representative of the less frail members of the original living population (Wood et al. 1992). Together, these issues directly impact population-level research, preventing direct inferences about disease, as well as health, in past populations from archaeological skeletal samples. With regard to infectious disease specifically, heterogeneity in frailty and selective mortality have been extensively explored for some diseases and disease events, but not yet estimated for others. Much of this research has focused on plague, caused by *Yersinia pestis*, specifically the fourteenth-century epidemic known as the Black Death. The short chronologies characteristic of mass graves created by epidemics have allowed researchers to reduce the role of confounding variables, such as temporal changes in diet and disease ecology, in investigating whether mortality from the plague was indiscriminate with regards to the age and previous health experiences of victims (see DeWitte and Stojanowski 2015). While archaeological skeletal samples with short chronologies, such as mass graves, are relatively rare, they were often produced by epidemics of acute disease in the past. These samples can therefore provide valuable opportunities to explore issues of selectivity and heterogeneity, and therefore increase the accuracy of estimating the impacts and dynamics of infectious disease in past populations, particularly for acute diseases that can otherwise be difficult to study archaeologically.

Biomolecular advances in the study of infectious disease in the archaeological record

Methodological advances, particularly in biomolecular research, have also greatly expanded

scholarly understanding of infectious diseases in past populations. Importantly, after the pioneering studies of pathogen aDNA in the 1990s and early 2000s, the application of biomolecular methods has matured and become highly sophisticated, resulting in theory-building, the examination of existing research questions, and the generation of new ones, rather than method-driven research. Biomolecular techniques have been applied to a growing range of infectious diseases, enabling identification and analysis of infectious diseases that do not affect the skeleton, or do not always do so in a distinctive or specific way. These include smallpox, influenza viruses, typhoid fever, schistosomiasis, typhus, cholera, and the plague. Used with more traditional macroscopic methods, biomolecular techniques have also increased the accuracy of diagnosis and expanded the areas for studying diseases that do affect the skeleton in more distinctive and specific ways, such as tuberculosis, leprosy, malaria, and brucellosis.

The evolution of pathogens and coevolution of pathogens and their human hosts

The detection of some infectious diseases, such as treponemal disease, through biomolecular methods remains largely elusive due to methodological and material issues, such as the sometimes poor preservation of aDNA in skeletal material. However, diverse sampling strategies and enrichment techniques may increase the range of infectious conditions that can be analyzed through pathogen genomics. Among other insights, biomolecular research on pathogens recovered from archaeological remains, particularly aDNA, contributes to scholarly understanding of the evolution of infectious disease by providing granular, time-stamped data for reconstructing phylogenies. These data in turn allow scientists to test hypotheses about the histories of human–pathogen coevolution and resulting adaptations (see *DNA: NEXT GENERATION SEQUENCING*). Much of this research has focused on comprehending the coevolutionary dynamics and shifts in patterns of human susceptibility to infectious disease that have occurred throughout

major economic and societal developments in human history. These investigations frequently integrate biomolecular data, particularly from ancient pathogen genomics, with direct skeletal data on infectious disease, as well as archaeological, historical and/or ethnographic data. These diverse lines of evidence allow scientists to reconstruct how changes in subsistence, economic development, and social practices and processes altered patterns of pathogen transmission, mortality and morbidity within human populations, and the survival and reproduction of pathogens (Harkins and Stone 2015).

The major economic and social developments being investigated include agricultural intensification and industrialization. Paleolithic foraging societies were likely characterized by a relatively low burden of infectious diseases. In the Neolithic, agricultural societies shifted to an epidemiologic regime with a relatively high burden of infectious diseases, particularly epidemic infections. The burden was associated with increased sedentism and population density, reduced environmental quality, and increased contact with domesticated animals. The latter yielded a rise in zoonotic infections (diseases transmitted from animals to humans), such as smallpox, many of which caused high mortality in human populations. This shift in epidemiologic regimes is known as the first epidemiologic transition. Comparisons between the epidemiologic baseline of the Paleolithic and the subsequent epidemiologic regime provide a useful platform for developing hypotheses about relationships between human–pathogen interactions and social and economic change (Armstrong, Brown, and Turner 2005). Importantly, analysis of past transmission events between animals and humans can also inform the reconstruction and modeling of human–pathogen interactions in present and future contexts, with direct implications for public health measures (Harkins and Stone 2015). The high burden of epidemic infectious disease was exacerbated by increasing urbanization and industrialization in developed nations. However, public health measures, improved nutrition, and medical advances led to declines in the burden in developed nations in the late nineteenth and early twentieth centuries, producing increasing longevity and an increased burden of chronic and degenerative disease. This shift is known as

the second epidemiologic transition (Armélagos et al. 2005). Analyses of this trend, which do not yet substantially incorporate biomolecular methods but rely primarily on historical material augmented by skeletal and archaeological data, enable comprehension of the complex dynamics that exist between urban environments, particularly relative to sanitation and public health measures, medical advances and practice, pathogens, and their human hosts.

Life Table Analysis

JEREMY J. WILSON

Indiana University–Purdue University Indianapolis,
USA

Population dynamics and demographic patterns are subjects of analysis that transcend the social, behavioral, and biological sciences. For archaeologists, research questions often revolve around population growth, stability or decline, gene flow and immigration, and the demographic and epidemiological transitions experienced by populations from the late Pleistocene through the Holocene. In this context, *abridged life tables* provide one means of assessing and comparing basic demographic patterns in past societies and of detecting bias and underrepresentation of age classes and sexes in excavated samples. Chamberlain (2006) provides useful instructions on how to develop life tables from skeletal data, including corrections for varying growth rates that are based on model life tables. The construction of a life table for an archaeological sample is typically predicated on the analysis of human skeletal remains from a site and, at minimum, on estimates of age at death for all well-preserved skeletons and of sex for the mature, reproductive-age individuals. Analysts are typically observing skeletal indicators of development, growth, or breakdown at the macroscopic level and translating those observations into an estimate of chronological age for each skeleton. The individual age-at-death estimates are then tabulated into pertinent age categories at the discretion of the analyst, who can now begin the development of an abridged life table for an archaeological sample.

Life tables were originally developed by demographers and actuary scientists and are best exemplified in policies such as social security and health insurance, where life expectancy and other factors (e.g., preexisting conditions) play critical roles in determining current and future costs and reserves. From cohorts of the living, basic life tables include the proportion

of living (c_x) and deaths (d_x), survivorship (l_x), the age-specific probability of death (q_x), and life expectancy (e_x) within researcher-specified age ranges (e.g., 0–1, 1–2, 2–5 yrs.). Provided large and representative skeletal samples, significant inferences and comparisons can be achieved in paleodemography. Importantly, the use of the term “abridged” in life tables reconstructed for past populations reflects the fact that all individuals examined are observed at the time of death, which is different from the situation reflected in the census-driven or cross-sectional life tables developed by demographers. As discussed below, this difference complicates the analysis and interpretation of life tables in archaeology, but does not suggest that wholesale abandonment is required. However, it is important to recognize what abridged life tables can and cannot effectively measure about past population dynamics.

Like other specializations in archaeology, the codification of paleodemography and the use of abridged life tables followed the processual turn in the discipline that occurred in the 1960s and 1970s. Acsádi and Nemeskéri (1970) were among the first to implement life tables in examining demographic patterns in a series of Hungarian skeletal samples, and they argued that life expectancy increased with the Neolithic revolution in central Europe. This work was soon followed by Weiss (1973), who published model life tables that assumed population stationarity (i.e., zero growth) and reflected the hypothetical gamut of age-specific mortality and fertility rates anticipated among traditional anthropological populations. The importance of Weiss’s simulations and of more recent research on demographic patterns in traditional populations cannot be overstated for scholars who endeavor to understand population dynamics and compare death assemblages from archaeological sites to known case studies of foragers, pastoralists, and farmers. Meanwhile, in the United States, life tables were used by a host of researchers during the 1970s. This included the highly influential studies of the diachronic skeletal samples from Dickson Mounds in Illinois (Lallo, Rose, and Armelagos 1980), where

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0348

agriculture was interpreted as having a negative impact on life expectancy and health among New World peoples who inhabited the region. Among the various life table measures calculated, life expectancy at birth (e_0), sometimes referred to as the mean age at death, was the primary focus of interpretation.

During the 1980s, life tables and paleodemography faced legitimate criticisms on several fronts; this resulted in a proactive debate that continues to this day. Methodologically, researchers astutely observed that the adult age estimation techniques used by practitioners were deficient and resulted in mortality profiles and life tables that resembled the age structure of the reference collection on which the skeletal aging technique(s) was developed. The result was a compression of the human lifespan into seven decades or fewer, large clusters of skeletons being estimated to have died between the ages of 30 and 50 and very few to have experienced senescence and old age (i.e., 65+ yrs.). Despite the fact that adult mortality rates varied in living populations, most abridged life tables yielded homogeneity, with minor differences in survivorship and life expectancy among adults in the associated skeletal samples. These outcomes suggested that old age was rare to nonexistent in the past, regardless of subsistence practices, population densities, disease ecology, and other factors of interest. Adult age estimation techniques continue to be refined and developed by practitioners in the archaeological and forensic sciences and there is a strong emphasis on establishing more accurate and precise estimates for the elderly. Progress on this front is exemplified in a volume edited by Hoppa and Vaupel (2002), where new age estimation and paleodemographic techniques are presented.

Concurrently, a second major criticism was leveled against abridged life tables as an appropriate means to assess differences in mortality within and between skeletal samples. Death assemblages are produced over varying lengths of time and catchment areas, not to mention sociocultural factors that dictate where specific individuals are buried and whether they are ultimately exhumed by archaeologists. In the context of cemeteries used for generations, fertility has a more significant impact on the age-at-death distribution (i.e., d_x) depicted in abridged life tables than mortality. Therefore, in the high-fertility

populations that likely characterized most of the Holocene until recently, life expectancy at birth, as presented in life tables produced in paleodemographic studies, is inversely correlated with population growth. The proportion of juveniles in death assemblages becomes a proxy measure of population growth, as recently illustrated by Bocquet-Appel (2011) for the Neolithic demographic transition.

Moving forward with life tables, the challenges are not insurmountable, as old skeletal data can be recalibrated and most age-at-death distributions have, at minimum, a heuristic value for researchers who attempt to identify systemic biases such as the underenumeration of infants or of the elderly. Given the quality of the data, hazard models provide a viable alternative to the tabulation procedures commonly used in the construction of abridged life tables. Contrary to life tables that require the estimation of numerous parameters, hazard models effectively capture the variability in mortality across of human lifespan, with a handful of parameters specific to the course of juvenile and adult mortality, while often accounting for the uncertainty associated with the original age estimation techniques. Furthermore, the estimated parameters of a hazard model can be used to calculate important vital statistics, such as age- and sex-specific life expectancies, survivorship, and the force of mortality. These estimates of past human population dynamics are of interest to a host of research areas beyond archaeology and have the potential to facilitate future interdisciplinary collaborations.

Malnutrition

ROBERT R. PAINE

Independent Researcher, Rome, Italy

BARRETT P. BRENTON

St. John's University, USA

The study of paleonutrition and paleopathology (see PALEOPATHOLOGY) provides an important time depth to the field of nutritional anthropology. Archaeological and skeletal evidence (see OSTEOLOGY) related to past diets, health, and nutrition brings home the holistic nature of a discipline that crosscuts the entire field of anthropology. The focus of this brief discussion centers on how the study of malnutrition and human skeletal biology came to the crossroads of human health, what has been done, and what could be accomplished. Malnutrition is a lack of a key component in one's diet. Traditionally, anthropologists have focused on several key components associated with bone health; these include iron and protein, and vitamins D, C, and B₃.

The study of ancient food-cultures that lack iron (see DIET AND TRACE ELEMENTS) as a key mineral associated with a healthy diet is seen in many publications concerning skeletal biology and malnutrition (Angel 1966; Stuart-Macadam 1992). In summary, the skeletal lesions often connected to chronic anemia (see ANEMIA) caused by an iron-diminished diet are porotic hyperostosis, cribra orbitalis, and long bone periostitis. This research has concerned itself with how anthropologists record, score, and define these lesions. Typically, small pits found on the skull are considered to be healed/inactive lesions, while hair-on-end lesions are active lesions. The debate continues as to what iron deficiency in ancient peoples truly reflects, that is, whether active lesions or healed lesions tell us a similar story. Other considerations still under discussion are how much of what is seen is specific to diet or parasitic causes or the result of epigenetic origins (see DIFFERENTIAL DIAGNOSIS).

Protein malnutrition is a key metabolic disorder (see METABOLIC DISEASE) for many past and present human communities (Goodman et al. 1988; Larsen et al. 2002). Protein-calorie malnutrition (PCM) refers to an inadequate calorie and/or protein intake. It is a dietary issue associated with a lack of meat, fish (see ZOOARCHAEOLOGY AND HUMAN DIET RECONSTRUCTION), and plant foods (high protein content). In living people, protein deficiency is often linked to low calorie intake; as such, the condition is referred to as marasmus, while kwashiorkor refers to a lack of protein with an adequate intake of calories. Skeletal lesions associated with PCM are also linked with general infectious agents (see INFECTIOUS DISEASE). Low protein intake often leads to an impaired immune system (Brinkey and Ives 2008). With an impaired immune system, individuals are subjected to a variety of infectious agents (bacterial and viral) that will affect bone biology. Skeletal lesions often associated with this interactive process include osteomyelitis and periostitis, the pitting and thickening of bone tissue.

A lack of vitamins may also influence health changes in bone. Vitamin C and its relationship to scurvy is well studied (Ortner and Eriksen 1997). Pitting on the sphenoid bone is considered one of the key skeletal lesions indicating a chronic lack of vitamin C. Ortner and others showed that vitamin C had been an overlooked dietary problem in subadult archaeological burials. Mays (2008) also provides an important summary specific to scurvy and vitamin C deficiency research. He notes, after prolonged and chronic episodes of scurvy in adults, that teeth are often lost and alveolar bone changes may occur. Unlike adults, children tend to show greater skeletal changes as a result of scurvy (Mays 2008). Ortner and Eriksen (1997) refer to this as infantile scurvy. They suggest that the cranial vault, eye orbits, the greater wing of the sphenoid, the maxilla, and the hard palate will show signs of pitting. Hence, when observed by anthropologists, the combination of these lesions is linked to scurvy in child burials.

Vitamin D deficiency affects bone and is associated with a diet lacking in foods that provide vitamin D (for example, eggs, milk, fish) and a lack of UV-light exposure. Ortner and Putschar (1981) provide an important early reference for this metabolic disorder. The authors refer to vitamin D deficiency (rickets) as a disease found in children, characterized as a lack of mineralized cartilage and bone. As a dietary disorder, it ranks as one of the top three micronutrient deficiency issues studied by paleopathologists (Brinkley and Ives 2008). This form of malnutrition has been linked to agricultural practices and the expansion of human communities in the northern climates of Europe. Today, we see this condition in communities with inadequate diets and little sunlight exposure. For example, among the impoverished of New York City or the poverty-stricken ethnic groups of India that practice *purdah*. *Purdah* is when married women are kept in isolation. When demineralization of bone under these conditions occurs in adults it is called osteomalacia. Along with studies that focus on current communities, there have been numerous key studies of rickets among historic communities, such as from the burials excavated from the St. Martin's cemetery and from the Spitalfield church cemetery (Brinkley and Ives 2008). Both studies link environment, cultural practices, and diet to the increase in rickets among these people.

Using a biocultural approach towards understanding human diet and health, Paine and Brenton (2006) have argued that innovative interpretations about the diet, health, and paleomalnutrition of New World horticulturalists should emerge from hypotheses concerning skeletal manifestations and associated lack of iron, vitamin C, and niacin; the latter is associated with a chronic dietary condition known as pellagra. Paine and Brenton (2006) re-examine the skeletal signatures (cranial pitting, periostitis of long bones, and cortical bone loss) traditionally linked to maize intensification, and they point out that there is little critical discussion concerning the potential effect of pellagra on ancient Native American peoples. A passing mention of the "possibility" of pellagra in ancient skeletal populations has been noted by Larsen et al. (2002, 411). To further explore this overlooked issue, Paine and Brenton

(2006) focused on the inner-workings of rib micro-anatomy. The authors found that the rib shows signs of dietary deficiencies both in cortical bone and micro-anatomy relative to age-at-death. These results show the promise of how rib micro-anatomy can highlight how bone responds to chronic and seasonal bouts of nutrient starvation. It appears that vitamin deficiencies lead to less cortical bone in ribs and a fewer number of key micro-anatomical features.

A key concern of researchers studying malnutrition from the bioarchaeological record is the long-running debate about the osteological paradox. This debate centers on two issues: Do bioarchaeologists have adequate demographics to assess skeletal health from burials of unknown individuals, and do the presence or absence of skeletal lesions provide accurate insight into human health of past peoples? Goodman et al. (1988) have stated that skeletal lesions reflect stress indicators and can be used to measure the quality of health of ancient populations. This claim, echoed by many other researchers, was brought to a critical evaluation by Wood et al. (1992). Wood et al. raised the question as to whether burials with skeletal lesions accurately reflect the health status of past populations specifically and whether skeletons with lesions represent extremely ill individuals or those who are considered survivors. Are survivors healthy or are they just getting by? If the individual dies without exhibiting skeletal lesions, does this mean that this death represents an acute illness or simply one caused by agents that do not affect the skeleton? Since 1992, these questions continued to be difficult to answer. At present, it is reasonable to suggest that many paleonutritionists work under the assumption that individuals who exhibit skeletal lesions have suffered from chronic stressors (sometimes from chronic dietary-related stress episodes), while individuals who die young with few or no skeletal lesions die from acute ailments (Goodman and Martin 2002). This is a critical point to base observations from while attempting to interpret dietary-related skeletal lesions seen among ancient burials. Most of the skeletal lesions specific to dietary deficiencies will occur only if the deficiency becomes chronic. Many of these episodes occur seasonally and therefore may have been less chronic and were

survivable. Hence, a broad range of lesion variability may often be seen as individuals undergo chronic stress episodes followed by periods of recovery.

Importantly, the study of paleonutrition should be based on a synergistic relationship between dietary deficiencies and infectious agents. A lack of specific nutrients, minerals, and vitamins diminishes one's ability to fend off infectious agents. As a result, many of the skeletal lesions observed are often the result of both nutrient deficiency and the insult by infectious agents. Only the archaeological/environmental context can help to sort out the multilayered causes that produce skeletal defects. Hence, biocultural/cultural ecology approaches to interpreting the health status of past peoples are invaluable.

The next generation of paleonutritionists should continue to challenge the dogma of the discipline. One means for doing so would be to focus research on collections of skeletal material with known demographics. A growing but yet underused resource for such studies is the skeletal material housed at several human body farms organized by universities found in Tennessee, Texas, Colorado, and North Carolina. Although these academic research facilities are primarily used to conduct forensic/decomposition studies, there is no reason why this skeletal material could not be used for the assessment of bony lesions associated with health-/dietary-related research.

Metabolic Disease

NICOLE E. SMITH-GUZMÁN

Smithsonian Tropical Research Institute, Panama

Metabolic disease, or metabolic bone disease, represents a suite of conditions that cause an imbalance in normal bone remodeling processes. These conditions are of increasing interest to bioarchaeology (see BIOARCHAEOLOGY) as they lie at the intersection of human culture and health. By definition, metabolic diseases have nutritional, cultural, social, or genetic (see GENETICS: ANCIENT) causes rather than infectious ones. Yet some metabolic diseases can affect susceptibility to certain infectious diseases (see INFECTIOUS DISEASE), and others may arise as sequelae (i.e., consequential secondary conditions) spawned by a chronic infectious disease. Metabolic diseases can affect the whole body, as is the case with the general bone density reduction of osteoporosis, or may be limited to only a few focal areas, as with Paget's disease of bone. Bioarchaeologists use osteological (see OSTEOLOGY) evidence of metabolic disease found on human remains to infer genetic and cultural similarities, as well as social and sex-based differences, within past human populations.

Metabolic diseases are caused primarily by a deficiency or surplus of a particular mineral or hormone required in the formation or resorption of bone tissue. During bone modeling and remodeling, specialized osteoclast cells are signaled by cytokines, growth factors, and hormones to resorb bone. This is followed by the signaling of specialized osteoblast cells which deposit new bone matrix called osteoid. Osteoid is composed of the organic component of bone, including mostly collagen fibers, and the nonorganic hydroxyapatite, which subsequently mineralizes the matrix.

The main minerals implicated in bone homeostasis are calcium, phosphate, and magnesium, which all play a role in bone mineralization as the principal components of hydroxyapatite

($\text{Ca}_5(\text{PO}_4)_3(\text{OH})$). Other necessary minerals less frequently implicated in problems of bone homeostasis include fluoride, sodium, potassium, strontium, and citrate. Often deficiencies in any of these minerals stem from dietary and environmental factors. The main hormones required for normal bone maintenance are vitamin D, estrogen, parathyroid hormone, and to a lesser extent calcitonin, thyroid hormone, and vitamin A. Deficiencies in many of these hormones result from normal age-related decreases in hormonal production, but can also result from environmental and dietary factors as well as certain congenital conditions (see CONGENITAL CONDITIONS) of metabolism. Many metabolic diseases cause similar patterns of nonspecific abnormal bone growth (i.e., periosteal reactions) or bone reduction (i.e., pitting), complicating the identification of the specific metabolic disorder in skeletal remains. The metabolic diseases described in detail in the paragraphs to follow include those identified in past populations through their unique skeletal manifestations.

Vitamin C is an important nutrient in immune response, absorption of iron, and the formation and maintenance of body tissues, especially collagen. It must be obtained from dietary sources, such as fresh fruits and uncooked vegetables. Vitamin C deficiency is known as scurvy, the consequences of which are dependent upon the age of the individual and the duration of the deficiency. Several symptoms arise as a result of the impaired collagen formation associated with scurvy. These include hemorrhaging, hemarthrosis (bleeding into the joints), hair loss, and depressed osteoblastic activity. The skeletal manifestations of scurvy that are visible in human remains from archaeological sites vary according to the age of the individual. In subadult individuals, chronic bleeding from scurvy can cause abnormal porosity of bone cortex (particularly affecting the sphenoid, mandible, maxilla, orbits, scapulae, and os coxae), new bone formation (affecting the orbits, cranial vault, long bone ends, and os coxae), dental enamel hypoplasias and antemortem tooth loss, and enlargement or fracture of ribs near the costochondral

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0372

junction. In adults, scurvy can result in new bone formation in the orbits and the ends of long bones, antemortem tooth loss and alveolar bone inflammation, vertebral osteopenia and possible biconcave compression, and transverse fractures of ribs at the costochondral junction (Brickley and Ives 2008).

Due to the role of vitamin C in iron absorption and its association with internal bleeding, scurvy and anemia (see ANEMIA) often exist as co-morbidities, complicating attempts to separate symptoms and skeletal effects caused by each condition. Similarly, scurvy's influence on immune system fitness leads to co-morbidities with infectious diseases that cause nonspecific skeletal reactions such as periostitis and osteomyelitis. Thus, a cautious approach must be taken in the paleopathology (see PALEOPATHOLOGY) of scurvy, including the description of a combination of probable scorbutic lesions, the weighting of the more unique lesions such as sphenoidal porosity, and the use of a rigorous differential diagnosis (see DIFFERENTIAL DIAGNOSIS). The use of scanning electron microscopy, for example, has been shown to successfully distinguish between the expansive *dipl e* of anemic orbital porosity and the periosteal reaction characteristic of scorbutic orbital porosity (Brickley and Ives 2006).

Evidence of scurvy has been reported at archaeological sites globally, including in areas with surprisingly ample dietary sources of vitamin C in the natural environment. These discrepancies between expected and observed nutrition of ancient populations have been attributed to the role of social control and structural violence influencing nutritional variation within and between populations, as well as nondietary factors such as infectious disease and parasitism (see PARASITOLOGY) (Halcrow et al. 2014). In these cases, paleoethnobotany and stable isotope (see PALEOETHNOBOTANY AND STABLE ISOTOPES) evidence of diet may serve to narrow the etiology of scurvy. However, these cases of the appearance of scurvy in unlikely environments speaks volumes to the potential underreporting of scurvy cases in paleopathology where mild scorbutic lesions may be disregarded or misinterpreted, and scurvy not considered in differential diagnoses. Due to the challenges surrounding scurvy's co-morbidities, its often nonspecific skeletal manifestation, and potential

for underreporting in the paleopathological literature, wider paleoepidemiological patterns of this metabolic disease in antiquity remain to be seen.

Vitamin D is necessary for immune reaction, mineral metabolism, cell growth, and cardiovascular health. It can be either produced by the body naturally through conversion of ultraviolet rays in the skin, or obtained through dietary sources such as dairy products. The deficiency of vitamin D, called either rickets or osteomalacia depending on the age of the individual, can cause hypocalcemia and poorly mineralized bone. As with scurvy, the skeletal manifestation of vitamin D deficiency varies according to the age of the person affected. In subadults, rickets causes delayed closure of fontanelles, thinned cranial bone, and frontal/parietal bossing, as well as layers of spiculated, irregular porous bone in the cranium. It also causes delayed dental eruption, hypoplastic defects, kyphosis or scoliosis of the vertebrae, enlargement of costochondral rib junctions and sternal protrusion, abnormal bending of the ribs, os coxae, sacrum, and long bones, and porosity, fraying, and enlargement of the metaphyses due to disorganized growth, which often leads to growth stunting. In adults, osteomalacia causes fine pitting of the cranium, antemortem tooth loss, kyphosis or scoliosis with biconcave compression of vertebral bodies, pseudofractures of the ribs and os coxae, long bones, scapulae, metacarpals, and metatarsals, and angulation or bending of the os coxae, long bones, scapulae, and ribs.

Evidence of rickets and osteomalacia has been reported at several archaeological sites, with most following the Industrial Revolution in the British Isles and northern Europe where manmade smog coupled with naturally limited sunlight during the winter months reduced the body's ability to manufacture vitamin D. As with scurvy, the effects of vitamin D deficiency on the skeleton are more severe in subadult individuals due to the mineral requirements of rapid bone turnover due to growth. The skeletal effects of rickets and osteomalacia may remain unnoticed in many cases, with very mild bending of the long bone shafts that only slightly enhances their normal bending morphologies. In environments allowing more ultraviolet ray exposure, these metabolic diseases of vitamin D deficiency may indicate cultural practices of prolonged breastfeeding (see

INFANT FEEDING) and inadequate exposure of high-social-class individuals to sunlight (Giuffra et al. 2015).

One of the most common metabolic diseases resulting from hormonal deficiency is osteoporosis. Osteoporosis describes a decrease in bone mass with subsequent increase in fracture risk associated with age-related decline in sex hormones of both men and women. Its skeletal manifestations include fine pitting, porosity, or thinning of the cranial vault, antemortem tooth loss or resorption of the alveolar margins, fractures of the vertebrae, ribs, pubic rami, distal radius, or femoral neck or trochanter, kyphosis, vertebral wedging, or biconcave deformities, and thinning of the ilia.

Osteoporosis can be difficult to identify with confidence in archaeological human remains. Several case studies have attributed skeletal changes to osteoporosis, but few studies have surveyed its presence at a populational level. Differential diagnosis of osteoporosis in paleopathology is complicated by its co-morbidity with scurvy and vitamin D deficiency, as well as its sometimes subtle skeletal manifestation (i.e., generally lightweight bones or noticeably dispersed trabeculae). Such a wider populational study could reveal influences of diet and activity level as evidenced by susceptibility to osteoporosis.

Paget's disease of bone refers to a chronic disease resulting in the disruption of bone remodeling in certain bones, characterized by skeletal enlargement. The cause of the disease is still uncertain, but it seems to have a genetic and perhaps infectious (viral) component. Its skeletal manifestations include enlargement or thickening of the cranial vault and vertebrae, hypercementosis or ankylosis of the teeth, fractures of vertebrae and long bones, deformities of the os coxae, bowing or widening of the long bones, and a bone surface texture similar to that of pumice stone.

Paget's disease of bone has rarely been identified in archaeological human remains, including at many sites in the British Isles, leading to the hypothesis that this disease originated in the region. Again, paleopathological reports of this metabolic disease have mainly consisted of case studies, with population-level prevalence unknown. Co-morbidities such as osteosarcoma co-occurrence with Paget's disease of bone are

likewise unexplored in past populations. With more regional surveys and meta-analyses, bioarchaeologists are poised to offer key details of the potential environmental and genetic factors that play a role in the disease.

Fluorosis is a condition caused by the surplus of fluoride in the body due to the ingestion of toxic levels. Fluorine substitutes for the hydroxyl ion in the hydroxyapatite crystal of bone and teeth, forming fluoroapatite, a more brittle structure. Fluorine also stimulates osteoblastic activity. The skeletal manifestation of fluorosis includes thick, heavy, and irregularly shaped bones (particularly the cranium and long bones), ossification of soft tissue attachments, ankylosis of the vertebrae and ribs, and teeth with white patches and possible pitting.

Fluorosis has been reported from archaeological sites in North America and the Middle East. Again, careful differential diagnosis considering combinations of skeletal lesions and the inclusion of environmental and epidemiological evidence is necessary to pinpoint fluorosis in past populations. With advances in human skeletal geochemistry (see HUMAN SKELETAL GEOCHEMISTRY) and portable X-ray fluorescence spectrometry (pXRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)), future analyses of fluorosis and other metabolic conditions may be bolstered by trace element analysis of bone, though caution must be taken to rule out confounding factors of postmortem mineral absorption from the soil.

Other, less common metabolic conditions include hyperparathyroidism, pellagra, starvation, hyperostosis, hypophosphatasia, osteogenesis imperfecta, and osteopetrosis. These conditions are not discussed here due to the rarity of their detection in human skeletal remains. Much is still unknown about the mechanisms and skeletal manifestations of metabolic disorders. With advances in clinical knowledge of the biological processes and effects of various chemicals on metabolism, bioarchaeologists will be able to identify more skeletal manifestations of metabolic disorders in osseous remains. Many metabolic bone diseases have overlapping skeletal manifestations, necessitating the use of multiple lines of evidence and differential diagnosis. With increased calls for increases in rigor in paleopathology, use of algorithmic methods

to account for lesion patterning in differential diagnosis, and incorporation of advanced imaging and mineral composition assays, metabolic bone disease is poised to feature more widely in future studies of skeletal pathologies and lifelong skeletal maintenance and well-being in past populations.

Mobility and Lead Isotopes

ASHLEY E. SHARPE

Smithsonian Tropical Research Institute, Panama

GEORGE D. KAMENOV and JOHN KRIGBAUM

University of Florida, USA

In recent years, lead (Pb) isotope ratios have become an increasingly powerful tool to track mobility in the archaeological record. Much like strontium, lead isotopic testing compares isotope ratios from human and other animal remains to known ratios in the bedrock of a geographic area as a means of identifying the place of origin of the individual. Combined with other sourcing techniques, lead isotope analysis allows archaeologists to more accurately identify where on the landscape a human or other animal moved during its life, providing archaeologists with an enhanced means of exploring such topics as seasonal mobility, immigration, exchange, communication, and other social relationships between regions. Isotopic detection of such activities is particularly useful among ancient societies that lacked written records that would otherwise attest for such movements.

Biogeochemistry of lead isotopes

There are three isotope ratios of lead that are commonly used in archaeology: $^{206}\text{Pb}/^{204}\text{Pb}$, $^{207}\text{Pb}/^{204}\text{Pb}$, and $^{208}\text{Pb}/^{204}\text{Pb}$. ^{204}Pb is a nonradiogenic isotope, while ^{206}Pb and ^{207}Pb are the radiogenic products of uranium decay (^{238}U and ^{235}U , respectively), and ^{208}Pb is the product of thorium (^{232}Th) decay. Lead isotope ratios in bedrock are determined by the original amounts of U, Th, and Pb in the rock, as well as the elapsed time since the rock formation. Unlike strontium and oxygen isotopes that are also used for tracing

mobility, lead isotope ratios in living organisms are not influenced by coastal ocean spray.

Although still not clearly defined, the most probable pathway for lead incorporation into animals, including humans, is through ingestion and/or respiration of dust and soil from the surrounding environment. Lead is incorporated into the skeletal tissues of animals, including teeth and bones. Unlike isotopes with lighter atomic masses, such as carbon and oxygen, lead isotopes do not fractionate, or separate by isotopic mass, in living organisms. Thus, the lead isotopic ratios in the bedrock of a region reflect the ratios in the skeletal tissue of an animal that lived in that region. Analysis of the lead ratios in tooth enamel apatite, which forms early in an animal's life, and unlike bone does not remodel later in life, can help identify the animal's place of birth. Similarly, bone tissue remodels over time, and so by testing the lead ratios in bone apatite, archaeologists can identify the lead isotope ratio average from the last few years of an animal's life. However, a major obstacle for using archaeological bone in lead isotopic studies is the possibility of postmortem diagenetic alteration (see *DIAGENESIS OF BONE*), such as from chemical changes brought on by extended contact with the surrounding soil. Enamel is a much denser substance, and its isotopic composition is less susceptible to diagenesis than bone. Because enamel in human teeth develops at different times during childhood and adolescence, comparing the lead isotope ratios between different eruption stages (i.e., first through third molars) can detect whether an individual moved to different locations during different stages of their youth.

Methods

The process of lead isotopic testing bears similarities to that of strontium, and the two can be tested from the same prepared sample. The extraction process from bone or enamel apatite takes place in a clean laboratory setting, minimizing the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0385

risk of contamination from modern lead in the environment. The lead isotopes in a sample are separated using an ion chromatography procedure, and are thereafter measured using either a thermal ionization mass spectrometer (TIMS) or, preferably, a multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS) (see ICP-MS AND MATERIAL ANALYSIS). NBS 981 is used as the standard for reproducibility.

Anthropogenic lead

Archaeologists who use lead for isotopic sourcing must be wary of contamination from modern anthropogenic lead. This may occur in the form of modern lead pollution; for example, archaeological human and other animal bones located near the surface of an urban area or near a location where leaded gasoline had been used, such as a road, might become contaminated with anthropogenic lead. Similarly, lead baseline studies should avoid using modern soil or plants, since these have high potential for contamination from anthropogenic lead. Bedrock is much more reliable for establishing baselines that can be applicable to the archaeological record, and archaeological soils may also contribute towards this end.

Applications

Lead isotope mobility studies have been used with increasing frequency now that there are more regional baseline maps available, developed by geologists and archaeologists alike. Many of these studies have been conducted in Europe, examining movements of humans throughout the Roman Empire and especially Great Britain (e.g., Shaw et al. 2016). In the Indus Valley region of Pakistan and northwest India, lead isotopes have been used to track the movement of adolescents as they migrated from rural to urban areas and between urban centers as a means of solidifying ties between developing communities over time (Valentine et al. 2015). Lead baseline studies are currently underway in Central America and the Andes as a means to investigate human and animal movements and exchange systems (Sharpe

et al. 2016; Turner et al. 2009). In the Caribbean, lead isotopes have been used in combination with strontium to track the introduction of animals to different islands by humans (Giovas et al. 2016). Some investigations have even made use of anthropogenic lead to track mobility, particularly studies detecting individuals in a population that may have been subjected to smelting activities, such as miners and metallurgists (Price et al. 2017). Lead isotopes are especially useful in tracking the introduction of metal smelting technology, particularly lead and silver, across different regions over time.

Lead isotope analysis has been used to track human mobility in modern forensic cases as well. Human skeletal remains recovered from the last century commonly exhibit modern lead isotope ratios derived from the leaded gasoline used in the individual's country of origin (Kamenov and Gulson 2014). Furthermore, twentieth-century human teeth show distinct lead isotope ratios when compared to archaeological populations from the same region. The natural lead isotope background in a given region can be rapidly altered once humans begin to mine and use lead. Therefore, in certain instances, archaeologists may need to use lead isotope data from ore deposits mined in antiquity as a baseline for tracking human mobility in the past.

Mobility and Oxygen Isotopes

LARKIN F. KENNEDY

Defense POW/MIA Accounting Agency (DPAA)
Laboratory, USA

Stable oxygen isotopes have great utility in archaeological provenience studies due to the high degree of geographic patterning in isotopic distributions. Heavier isotopic species of oxygen (^{18}O versus ^{16}O) are discriminated against during changes of state reactions in water (see ISOTOPES). This means that isotopic fractionation (differential rate of reaction by isotope mass) occurs during the production of water vapor from liquid water and vice versa, and the natural distribution of the isotopes of oxygen is a result of the balance of evaporation and condensation. In the hydraulic cycle, the majority of meteoric water evaporates from the ocean near the equator, providing a baseline oxygen isotopic ratio, and depletion of ^{18}O occurs as this water vapor condenses during precipitation and re-evaporates. The stable isotope ratio of water is reported in terms of $\delta^{18}\text{O}$, or the $^{18}\text{O}/^{16}\text{O}_{\text{sample}}$ ratio by departure from standardized ocean water $^{18}\text{O}/^{16}\text{O}$, measured in units permille (‰). Isotopic ratios in precipitation become progressively lower with distance from main water sources as the heavier isotope “rains out.” Since colder air has a reduced carrying capacity, increased altitude and latitude also result in lower isotopic ratios. A worldwide network of meteorological stations has measured the isotope values in monthly precipitation since the 1960s and summarizes this spatial variability (IAEA/WMO 2017).

This patterning allows one to discriminate among locations with broad climatic differences, meaning that stable oxygen isotopes act as a biological tracer. Often, yearly average $\delta^{18}\text{O}$ values in rainwater can be used to estimate the isotopic composition of local drinking water. In mammals, body water $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_{\text{bw}}$) is primarily governed by water intake and thus directly

reflects the values in precipitation. After oxygen is taken up in drinking water, metabolic functions incorporate it into different tissue types such that their $\delta^{18}\text{O}$ values are characterized by that of body water (Koch 2007).

In archaeological samples, original isotopic values are often retained in carbonate and phosphate of enamel and bone, resulting in their use as a geographic provenance indicator (Koch 2007) and in paleoclimatology. Other biological tissues, such as hair and fingernails, may also be analyzed from mummified remains. In skeletal tissue, phosphate comprises a large component of the mineral phase of bone or apatite ($\text{Ca}_{10}[\text{PO}_4]_6[\text{OH}]_2$) and carbonate substitutes for hydroxyl and phosphate groups (LeGeros 1981). The overall precision of phosphate in discriminating between water sources may be better than that of carbonate, and phosphate is also considered more resilient to inorganic alteration. However, carbonate may be more resistant to microbial alteration and its treatment and analysis is relatively easier and lower in cost.

Analysis of different tissues yields $\delta^{18}\text{O}$ values that reflect when these tissues formed during an individual's lifespan (see HUMAN GROWTH AND DEVELOPMENT and DENTAL DEVELOPMENT). Since cortical bone remodels over time, bone $\delta^{18}\text{O}$ slowly changes in response to local conditions and may provide an estimate of geographic residence near time of death. Enamel does not remodel and reflects the geochemical signature of an individual's place of residence during childhood development of the enamel crown. Thus, it may be possible to detect shifting geographic residence patterns by analyzing bone(s) and enamel in tandem from a single skeleton. Alternatively, since enamel formation is an incremental process, sequential samples from enamel layers or different teeth may be used to characterize seasonal movement in highly mobile populations.

Methods

Sample treatment differs for bone versus enamel, since alteration of the chemical composition of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0386

apatite is reduced in enamel and contaminants from the burial environment are more easily removed from this material (see *DIAGENESIS OF BONE*). The sample amount required for analysis is also tissue specific, and broadly based on estimates of molecular content per weight-percent (LeGeros 1981). An isotope ratio mass spectrometer (IRMS) measures oxygen isotope ratios in samples, and reports $\delta^{18}\text{O}$ relative to a material-specific standard (see *MASS SPECTROMETRY (MS)*). Common methods of diagenesis monitoring include obtaining the concentrations of trace elements often introduced into or leached out of bone or enamel during chemical alteration, or identifying postmortem changes in apatite crystallinity.

Defining local ranges

Isotopic results are compared to expected values through use of conversion equations. Isotopic spacing between body water and phosphate and the offset between $\delta^{18}\text{O}$ in phosphate and $\delta^{18}\text{O}$ in carbonate are linear. These relationships are assumed to be stable since carbonate and phosphate are thought to precipitate from the same body water pool with a constantly renewed and therefore constant $\delta^{18}\text{O}_{\text{bw}}$ value (France and Owsley 2015; Daux et al. 2008). The resulting conversion equations allow direct comparison of archaeological populations, or conversion of $\delta^{18}\text{O}$ from biological tissue to $\delta^{18}\text{O}_{\text{bw}}$. This value can then be compared to the modern isotopic composition of rainwater as interpolated by models accounting for latitude, longitude, and elevation (IAEA/WMO 2017).

However, the local range in $\delta^{18}\text{O}_{\text{bw}}$ is unlikely to exactly match local meteoric water $\delta^{18}\text{O}$, making it imperative that samples accurately represent the “local” $\delta^{18}\text{O}$ signal in biological tissue. In some cases, this discrepancy is due to averaging effects, for example, seasonal rainfall patterns may determine the $\delta^{18}\text{O}$ of drinking water, or humans may consume foods grown or foddered from a variety of local environments. In modern humans, variability in isotopic ratios is thought to be dependent on geography as well as human behavior (Daux et al. 2008). High mobility in an alpine area may result in high standard deviations

for “local” $\delta^{18}\text{O}_{\text{bw}}$. For archaeological samples, a conservative range of 2‰ has been traditionally used to represent nonmobile populations, but this range can also be determined using the distribution of experimental data (Wright 2012). For this method, a population sharing the same water source should display a normal distribution in $\delta^{18}\text{O}$ values as incorporated into body tissue, and any migrants will be statistical outliers. These methods for migrant identification depend, however, on the geographic origin of nonlocals being isotopically distinct from that of locals.

Cultural practices

Overlapping local ranges due to similar climatic conditions, high local mobility, and dietary or cultural practices may all preclude migrant identification. The use of open containers for storing drinking water allows evaporation and lead to enrichment in the heavier isotope of oxygen. The practices of brewing or stewing enhance this fractionation effect (Brettell, Montgomery, and Evans 2012). Consumption of processed fruits such as in olive oil or wine may also cause enrichment in ^{18}O (see *PALEOETHNOBOTANY AND STABLE ISOTOPES*), and when imported these products retain the $\delta^{18}\text{O}$ signature of their geographic origin. These cultural practices may significantly impact the $\delta^{18}\text{O}_{\text{bw}}$ in archaeological samples.

Breastfeeding may also result in enrichment of the oxygen isotopic composition of enamel. Since human societies conclude weaning at different ages (see *INFANT FEEDING*), this means that the $\delta^{18}\text{O}$ of enamel mineralized during early childhood may reflect the $\delta^{18}\text{O}_{\text{bw}}$ of the mother in addition to the $\delta^{18}\text{O}$ of local drinking water. Oxygen isotopes may thus be used to track the onset of weaning in a population, and tooth choice is an important factor in mobility studies.

The sensitivity of $\delta^{18}\text{O}$ to both geographic location and cultural factors makes it a powerful tool in human mobility research. Both bones and teeth regularly retain oxygen isotopic ratios which reflect geographic patterning, and many analytical methods are available for their study. Limitations in this isotopic tracer may be avoided by sample choice, and by combining oxygen isotope analysis with other isotopic systems,

such as lead (see MOBILITY AND LEAD ISOTOPES), strontium (see MOBILITY AND STRONTIUM ISOTOPES), or trace elements. These geochemical characterizations of geographic origin in mobility studies form an important component in understanding ancient life histories.

Mobility and Strontium Isotopes

KRISTIN K. HOFFMEISTER

Texas A&M University, USA

Reconstructing the mobility patterns of archaeological populations is a challenging task that many traditional avenues of inquiry cannot directly address. Radiogenic strontium isotope analysis ($^{87}\text{Sr}/^{86}\text{Sr}$) offers a direct way to analyze mobility using the isotopic composition of human skeletal remains. Since the introduction of $^{87}\text{Sr}/^{86}\text{Sr}$ analysis in archaeology by Ericson (1985), this technique has been widely applied to examine the movement of past groups in past societies throughout the world. Current research uses radiogenic strontium isotopes to examine population dynamics, exchange, conflict, sociopolitical organization, and cultural interactions. Beyond assessments of human mobility in the past, researchers also use $^{87}\text{Sr}/^{86}\text{Sr}$ to study the movement of fauna, artifacts, and food recovered at archaeological sites. Currently, most mobility studies on archaeological populations use strontium isotope analysis of bones and teeth in conjunction with other isotopes such as oxygen and lead (see MOBILITY AND LEAD ISOTOPES and MOBILITY AND OXYGEN ISOTOPES). In areas with regionally diverse diets, stable carbon and nitrogen isotopes have also been used with strontium data to obtain nuanced interpretations of mobility patterns (see DIET AND CARBON ISOTOPES and DIET AND NITROGEN ISOTOPES).

Strontium is an alkaline earth element that has four naturally occurring isotopes: ^{84}Sr , ^{86}Sr , ^{87}Sr , and ^{88}Sr . One of these isotopes, ^{87}Sr , is radiogenic and forms from the radioactive decay of rubidium (^{87}Rb), which has a half-life of 4.88×10^{10} years (Faure and Mensing 2005). The ratio between ^{87}Sr and ^{86}Sr (written as $^{87}\text{Sr}/^{86}\text{Sr}$) is of interest to mobility researchers because it is patterned geographically due to underlying geologic differences in the ratio of Rb/Sr and the ages of the rocks. Very old rocks with a high original Rb/Sr

ratio will have higher $^{87}\text{Sr}/^{86}\text{Sr}$ values, while younger rocks with low Rb/Sr ratios have lower $^{87}\text{Sr}/^{86}\text{Sr}$ values (Faure and Mensing 2005). These base differences in $^{87}\text{Sr}/^{86}\text{Sr}$ are incorporated into soils and groundwater via weathering processes. Strontium subsequently enters the food web with negligible biological fractionation, such that the foods and water in an area will have an $^{87}\text{Sr}/^{86}\text{Sr}$ value broadly consistent with the local geology.

Upon entering the body from food and water, the majority of strontium in the body is stored in the mineral component of bone, called hydroxyapatite, where strontium substitutes for calcium. Overall, less strontium is absorbed than calcium relative to what is available in the diet, a process called biopurification. This effect is magnified moving up trophic levels, such that carnivores have lower Sr/Ca than do plants and herbivores. The net result of this process is that the variance of $^{87}\text{Sr}/^{86}\text{Sr}$ is reduced in skeletal remains compared to soils and plants, and the $^{87}\text{Sr}/^{86}\text{Sr}$ of skeletal tissue reflects an average of dietary intake as the tissues develop. Thus, the $^{87}\text{Sr}/^{86}\text{Sr}$ of human remains is determined by the $^{87}\text{Sr}/^{86}\text{Sr}$ of items consumed, which in turn reflect the local geology, allowing for reconstructions of paleomobility (Bentley 2006; Ericson 1985).

When dealing with skeletal collections, there are two tissues available for strontium isotope analysis: dental enamel and bone (see HUMAN SKELETAL GEOCHEMISTRY). Human dental enamel forms during childhood and does not remodel during the lifetime of an individual. As a result, the $^{87}\text{Sr}/^{86}\text{Sr}$ of an individual's enamel represents their geographic location while the enamel was forming. The final teeth to develop in humans, third permanent molars, complete amelogenesis around age 13 years, so the $^{87}\text{Sr}/^{86}\text{Sr}$ of enamel represents an individual's location during childhood. In contrast, human bone is constantly remodeling such that the $^{87}\text{Sr}/^{86}\text{Sr}$ of bone reflects an individual's place of residence prior to their death. The tissue selected for analysis often depends on concerns about diagenesis (post-depositional chemical alteration of the tissue). In areas with poor preservation,

DOI: 10.1002/9781119188230.saseas0387

researchers often choose to only sample enamel to ensure the integrity of their data (Wright 2005). Alternatively, researchers can sample both tissue types to compare the geographic location of an individual during childhood versus the last years prior to death (Ericson 1985). This latter type of analysis allows for a nuanced look into mobility patterns over the lifetime of an individual.

With increasing use of strontium isotopes to reconstruct mobility, researchers have also identified several challenges to $^{87}\text{Sr}/^{86}\text{Sr}$ studies. One of the primary difficulties researchers encounter when analyzing strontium isotope data is the establishment of a “local” range of $^{87}\text{Sr}/^{86}\text{Sr}$ values for a given archaeological site. The soils in an area can vary substantially in $^{87}\text{Sr}/^{86}\text{Sr}$ values depending on the mineral composition of the soil, differential weathering patterns, water movement, and other environmental influences on individual minerals in the soil. Thus, it is difficult to use the $^{87}\text{Sr}/^{86}\text{Sr}$ of soil to establish a local strontium signature (Price et al. 2002). However, although local soils can have variable strontium isotope values, faunal skeletal remains often have homogeneous $^{87}\text{Sr}/^{86}\text{Sr}$ values due to averaging of local variability within the animal’s grazing range that allow researchers to establish a local $^{87}\text{Sr}/^{86}\text{Sr}$ range. Price et al. (2002) suggest using small-bodied animal remains to gain a baseline $^{87}\text{Sr}/^{86}\text{Sr}$ range for assessing human mobility patterns rather than referencing local geologic substrates directly. In the absence of faunal data, researchers have also looked to the statistical distribution of human $^{87}\text{Sr}/^{86}\text{Sr}$ values to define a local $^{87}\text{Sr}/^{86}\text{Sr}$ range (Wright 2005). Identifying a local strontium signature in this manner assumes that the local population was primarily consuming food and water from nearby sources and did not heavily rely on imported foods which might have a very different $^{87}\text{Sr}/^{86}\text{Sr}$ value.

In addition, the precise identification of a place of origin for migrants is frequently impossible using $^{87}\text{Sr}/^{86}\text{Sr}$ data alone. Quite disparate geographic regions can have identical $^{87}\text{Sr}/^{86}\text{Sr}$ values, limiting the precision with which researchers can identify nonlocal people. However, using additional isotopes such as stable oxygen, lead, carbon, and nitrogen isotopes in conjunction with strontium data allows for

greater identification of mobility patterns in ancient populations (Knudson and Price 2007).

Since the introduction of $^{87}\text{Sr}/^{86}\text{Sr}$ analysis in archaeology, researchers have made substantial contributions to understanding ancient mobility patterns, although there is ample room for future research. Traditional sampling strategies require 5–20 mg of bone or enamel, limiting the application of isotopic analysis on sensitive or rare specimens, such as early archaeological sites or fossil remains. New techniques, such as sampling via laser ablation, substantially limit the destructive nature of isotopic analysis, potentially providing new arenas in which these techniques could be applied (Copeland et al. 2008). In addition, the geographic distribution of $^{87}\text{Sr}/^{86}\text{Sr}$ values is largely unknown for many regions of the world. Further documentation of $^{87}\text{Sr}/^{86}\text{Sr}$ values will greatly enhance the utility of this isotope for reconstructing mobility in archaeological populations. Furthermore, the $^{87}\text{Sr}/^{86}\text{Sr}$ of different foodstuffs is poorly documented. A better understanding of the $^{87}\text{Sr}/^{86}\text{Sr}$ in likely dietary items could help elucidate $^{87}\text{Sr}/^{86}\text{Sr}$ patterning in archaeological populations.

Mortuary Analysis

GORDON F. M. RAKITA
University of North Florida, USA

It is an often repeated observation that there is more anthropological information per cubic meter of a human burial than any other type of archaeological feature. However, with this density of data come interpretive hurdles. The characteristics that make human mortuary deposits rich sources of information about past societies are inherent in an archaeological feature with both biological and sociocultural content. Thus it is not surprising that the ways archaeologists have interpreted data recovered from human burials is similarly complex. Data from burials have been examined for answers to some of the key questions prehistorians have asked and mortuary analysis has figured prominently in debates between scholars. As the goals of theoretical paradigms in archaeology have differed, so too have the ways researchers utilized mortuary data. At various times the focus has been on reconstructing ancient social structure and organization. At other times, interpreting the ideological or religious meaning behind various treatments has been paramount. Thus the various approaches to mortuary analysis have tracked the ebb and flow of theoretical developments within archaeology. Moreover, human burials have figured prominently in recent interactions between descendant communities and archaeologists.

In the United States, mortuary analyses were initiated by none other than Thomas Jefferson, who trenched a Native American burial mound near his home at Monticello (probably in 1783). The purpose of his excavation was to determine the manner by which the mound, and others like it, was constructed. Differences in the observed strata, superposition of materials, and the arrangement of skeletal remains indicated to him that the mounds were formed by accretion as the community interred their dead over time. Jefferson's approach has been

lauded as an early example of problem-oriented, careful archaeological excavation designed to test hypotheses and an approach that would easily be described as mortuary archaeology.

In Europe, during the late eighteenth and early nineteenth centuries, mortuary analysis was used in the development of chronological schemas. The antiquarianism of the late eighteenth century included a growing interest in graves. Hundreds of barrows and burial mounds were excavated. Analyses involved developing typologies of graves and chronologically sorting them on the basis of stratigraphy and an early form of relative dating. Christian Thomsen, a Dane, was able to refine chronologies through the examination of what he called "closed finds." These were assemblages of artifacts from features, frequently burials, which could be presumed to have been deposited at a single point in time. The Scandinavian chronologies developed by Thomsen and his student Jens Worsaae and the techniques that produced them were later extended across Europe. W. M. F. Petrie used a similar technique for sorting hundreds of Pre-Dynastic graves on the basis of changes to pottery form and design. In the early twentieth century, the analysis of burials for purposes of constructing chronologies was continued by culture-historians in the Americas. For example, Alfred Kidder used burials recovered at Pecos Pueblo to help define and refine his chronological sequence. Chronology was the focus of both Old and New World prehistorians and would remain so until basic culture-historical sequences of the various culture-areas were established.

The 1960s processual "New Archaeology" revolution ushered in an ambitious approach to human burials (Brown 1971). Sometimes referred to as the "representationalist" approach, processualists sought to reconstruct the social status of the deceased and in doing so assess the sociocultural complexity of the community. The approach assumed that the deceased's status was mirrored or "represented" in their mortuary treatment, particularly in the quantity and quality of grave offerings and energy expended on the burial. The more lavish the offerings, the higher

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0390

the status of the individual. Cemetery samples containing a range of offerings suggested social hierarchies, while those containing no variation indicated egalitarian societies. Scholars following this approach often use statistical clustering techniques to examine mortuary data for evidence of hierarchy. This perspective continues to be utilized by archaeologists to make claims about social organization in prehistoric communities and there are reasons to expect that in some contexts these claims are correct.

In the 1980s, mortuary analysis was one of the battlefields for the postmodern critique of the processual approach. These post-processualists used ethnographic and historical examples to demonstrate that there are contexts where mortuary practices are not a simple reflection of social statuses. In these cases, expenditures on the grave are not isomorphic with the deceased's status and sometimes diverge drastically from it. These divergences occur because the dead do not bury themselves but rather are buried by the living who use the occasion of a death as an opportunity to communicate and negotiate among themselves. Post-processualists advocated for the contextual, interpretive "reading" of burials as meaningfully constituted cultural texts. Further, this viewpoint on mortuary data foregrounds the mortuary rite as a performative event that is used for social and/or political machinations and to convey information.

Adding a diachronic perspective to mortuary analysis, Aubrey Cannon (1989) provided case studies which demonstrated that funerary treatments can oscillate from periods of high elaboration to periods with more understated displays. These cycles of ostentation occur as social groups appropriate the funerary practices of other groups as a way of appropriating their class or cultural identity. In response, the mimicked group will abandon their traditional practices for an alternative one in an effort to maintain a clear distinction. Further mimicking follows, leading to adoption of new practices and so on. This cyclical process explains why mortuary practices provided such useful chronological markers for the antiquarian and culture-history archaeologists. It also explains why in some cases the processual viewpoint is applicable and why in others it is not.

In some regards, the Marxist approach is an extension of the post-processual movement in that it recognizes mortuary treatments as enactments of and by society that may not faithfully mirror social, economic, or political reality. Burials, from a Marxist point of view, represent deposits of social labor. Deployment of surplus labor in mortuary contexts might indicate status inequality or it may mask that inequality. Moreover, different objects or treatments used within a burial may have different social value on the basis of the labor needed to produce them. Therefore, Lull (2000), for example, recommends a comparison of consumption of products in nonmortuary contexts versus the funerary context in order to elucidate socioeconomic and socio-ideological structures within the society.

In the 1990s, a new interest in ancestors and ancestor-hood emerged in the archaeology of death. Inspired by the work of Max Gluckman, Robert Hertz, Arnold Van Gennep, Ian Morris, Richard Huntington, and Peter Metcalf, mortuary analysts began to focus on how "ancestors" differ from simply the dead. This approach recognizes that in many societies death does not automatically confer ancestor-hood on an individual. Indeed, Gluckman makes a distinction between "cults of the dead" which represent rites of passage marking the transition from life to death and "ancestor cults" which establish someone as an ancestor with an active role in the lives of the living. Examinations of postmortuary rituals and evidence of continued interactions with the deceased continued into the 2000s and were supplemented by other topics. These included explorations of mortuary rituals and their role in social memory, identity and personhood, gender and age, embodiment, and the location (space and place) of burials. Throughout the 1990s and 2000s, the overarching guideposts for mortuary analyses included the heavy use of ethnographic data to inform interpretations of archaeological cases, an acknowledgment of the agency of the living in dealing with the dead, and a recognition that mortuary practices are performative (Rakita and Buikstra 2005).

The second decade of the new century has seen two significant developments in mortuary analysis. The first is a re-emphasis on the importance of detailed observation of in-situ materials

and a clarification of terminology used to make those observations. Knüsel (2014) described archaeothanatology, an approach advocated by Henri Duday that involves the careful excavation, recording, and analysis of human skeletal remains in order to identify signs of funerary behavior and taphonomic processes. Where the archaeothanatomical approach is particularly useful is in focusing attention on the careful excavations and observations that can tell us about the processes that happened from the moment of interment to the moment of excavation. Reconstructing this process should allow for better reconstruction of the moment of the burial (which has considerable cultural content).

The second development is a trend towards greater integration of mortuary and bioarchaeological data. Processual archaeology and its more optimistic view of mortuary analysis was an important influence on the development of bioarchaeology (see BIOARCHAEOLOGY) which itself has had a significant impact on the amount of information gleaned from skeletal remains from mortuary contexts. However, for decades, consistent and deeply integrated analyses of data from both mortuary contexts and human remains were rare. More recently there has been greater emphasis on comparing archaeological derived data with information gleaned from osteological analyses. For example, Quinn and Beck (2016) recommend comparisons of mortuary and bioarchaeological data to assess coherence between lived and performed identities. They explore the interpretive possibilities of coherence between archaeological and biological signatures of inequality (interpreted as institutionalized inequality) and equality (interpreted as egalitarian contexts). Alternatively, dissonance between the two datasets might indicate mortuary practices that mask lived inequality or mortuary practices that exaggerate inequality that may not have been as extreme for the living.

Increased engagement with the ethnographic literature on mortuary practices has also led to a greater awareness of the importance of the dead in the lives of the living. Burials are important to descendant communities and this has played out in the political arena (Kakaliouras 2008). Many feared that the passage of the Native American Graves Protection and Repatriation Act (NAGPRA) would sound a death knell for

mortuary studies. And while excavations of large numbers of burial features have become rare in the United States, there has been a remarkable upswing in bioarchaeological publishing (Rakita 2014) possibly due to the publication of the “Standards” for collecting data from skeletal remains (Buikstra and Ubelaker 1994) and the recordation process mandated by NAGPRA. Thus, far from deterring bioarchaeological work in the United States, NAGPRA has ushered in an era of growing application of bioarchaeological methods to examine prehistoric and historic human populations. Intriguingly, NAGPRA has also encouraged archaeologists to regard human remains and their associated artifacts as inseparable and equally important components that must be cared for together. The Act has led to greater collaboration between mortuary analysts, bioarchaeologists, and descendant communities.

Musculoskeletal Stress Markers

SHIORI YONEMOTO

Kyushu University, Japan

A great deal of effort has been put into reconstructing the daily life and physical activities of past populations in both physical anthropology and bioarchaeology. Researchers have long been interested in identifying occupational specialization by analyzing skeletal remains. Hawkey and Merbs (1995) used the term musculoskeletal stress markers (MSMs) to refer specifically to distinct changes at sites where muscles, tendons, ligaments, and cartilage attach to bone. The scores for MSMs, which range from 1 to 6, are based on the complexities of the surface shape at each attachment site, and are used for statistical analyses. It is important to compare differences in the patterns and profiles of MSMs using multivariate analysis, line graphs, and frequency distribution. These comparisons reveal differences in physical activity from the differences in MSM scores. All studies on MSMs have essentially been based on the principle of bone functional adaptation; that is, bone form reflects the cumulative effects of intra vitam mechanical loading or strain. Recently, the more neutral term “entheseal changes” was adopted at a workshop on MSMs that was held in 2009 at the University of Coimbra in Portugal. This neutral term was suggested to alleviate doubt regarding the correlation between MSMs and physical activities. Although the standards created by Hawkey and Merbs (1995) make it possible to rank scores based on entheseal severity, many researchers are often criticized for not taking into consideration the histology and organization of MSMs. The Coimbra group proposed a new scoring method based on the current understanding of the etiologies associated with these osseous changes. Entheses are now classified as either fibrocartilaginous or fibrous entheses according to the tissue type. The Coimbra group distinguished two

histological zones between the margin and the rest of the enthesis at each attachment site, and listed the alterations and features visible in each zone. This method has an advantage in that intra- and interobserver errors are small; however, the data cannot be ranked.

For both scoring methods, caution is warranted because similar scores at different sites do not necessarily imply similar degrees of exposure to biomechanical stress. One solution is to compare the patterns and profiles of MSMs using multivariate analysis and line graphs. MSMs scored using the Hawkey and Merbs method were the first to reveal unique MSM patterns of watercraft-using fishermen in various populations. Further, MSMs clearly correlate with the lifestyles based on socioeconomic status in a hierarchical society (Yonemoto 2016). This finding indicates that the effect of social hierarchy is manifested in MSMs, because lifestyles are regulated according to hierarchy.

However, many researchers still have questioned the validity of their correlation with physical activity, because MSMs are affected by various factors, including age, sex, and body size. These studies that have examined MSMs have several shortcomings. Many of these studies were conducted using only aggregate MSM scores. These scores only indicate whether the applied load was large or small. Although aggregate measures may be useful for reducing the error range and enhancing methodological validity, similar scores at different sites do not necessarily imply similar degrees of exposure to biomechanical stress. The aggregate scores could potentially prevent entheseal changes from being used as an indicator of the different ways past populations moved their bodies.

Moreover, age, and not physical activity, has been identified as having the highest correlation with entheseal changes. This age correlation could be related to the stresses that accumulate over the course of an individual's life. While this may be true, age cannot be regarded as the only factor that affects MSMs. Yonemoto (2016) noted that the degree to which age affects MSMs is dependent

on cultural, social, and subsistence activities. This means that differences can be attributed to age group, as the chronological age of an individual in these societies likely contributed towards activities performed by that individual. Sex has been identified as having a high correlation with enthesal changes. The degree to which sex affects MSMs might also be population-specific, like the effects from age, because the activities of men and women are regulated by sexual division of labor.

The biggest challenge facing MSM studies is linking specific skeletal conditions to the development of attachment sites. Identical MSMs on skeletal remains from different locations are often ascribed to different physical activities; therefore, studies of MSMs are criticized as being “just-so stories.” It is impossible to understand a person’s life based only on a specific activity because all human life is a series of complex physical activities. Researchers should not be quick to assume that a similarity in MSMs among different populations points toward commonality in their physical activities.

Then what are MSMs useful for? It is necessary to examine the differences in the physical activities among social divisions and how age and sex affect MSMs. Furthermore, the degree of differences in MSMs among social groups should be compared between societies with different social organization, such as egalitarian, stratified, and hierarchical societies. In doing so, it may be possible to distinguish, for example, a skilled producer and an aristocrat from laborers. Such studies are meaningful because they relate to the

historical development of social inequality. The differences in these social divisions expressed by physical activities among various groups should be examined. By examining the differences in behavior patterns, MSMs may be a promising means for revealing correlations between characteristics of behavior patterns and social structure.

Oral Health

JOHN R. LUKACS

University of Oregon, USA

The oral health of past populations is of interest to archaeologists because it involves both biological and behavioral factors. Anthropologists focus on cultural and behavioral variables affecting oral health. These include subsistence, food choice, and food processing methods. Sex and social status differences in food type and frequency of consumption also affect dental disease rates. By contrast, biological forces affecting oral health include the nutritional value and chemical composition of food. The biology of sex impacts oral ecology by causing differential susceptibility to dental disease in men and women. The World Health Organization (WHO) International Classification of Disease lists 14 diseases of the oral cavity. Because teeth preserve well in archaeological samples, many pathological dental conditions are easily observed in calcified tissues and can be diagnosed in teeth and jaws of skeletons from archaeological contexts (see PALEOPATHOLOGY and TAPHONOMY). Four dental lesions will be considered here: one developmental lesion (enamel hypoplasia (EH)) and three degenerative lesions (dental caries, antemortem tooth loss (AMTL), and periodontal disease). Because EH forms in childhood during growth of dental tissues it is a developmental disease. This contrasts with dental diseases resulting from infection or decay, such as dental caries, AMTL, and periodontal disease. The prevalence of pathological dental lesions, associations between types of lesions, and the sequence of dental diseases during an individual's life depend on biological and cultural/behavioral factors. These include mode of subsistence, extent of food processing, and frequency of food consumption, factors that often vary by sex or social status. Insights gained from the analysis of EH are followed in this

entry by a focus on dental caries and associated degenerative pathological lesions.

Enamel hypoplasia is a reduction in enamel thickness due to a temporary disruption in the secretion of enamel matrix by ameloblasts (enamel-producing cells). Secretory phase ameloblasts are sensitive to stressors such as undernutrition, febrile disease, infection, and trauma (see INFECTIOUS DISEASE and MALNUTRITION). When enamel matrix is fully mineralized it remains unchanged and unaltered for life with few exceptions: dental wear and cultural modification (etching and inlays, see DENTAL DECORATION). Hence, EH provides an indelible and retrospective record of systemic physiological disruption in an individual's growth and development (see HUMAN GROWTH AND DEVELOPMENT). Due to these attributes, EH has been the focus of intense study to gain insight into group differences in relative health of past populations. EH is expressed as a linear indentation or groove of varying depth and width on the outer enamel surface encircling the tooth crown (Figure 1a,b), hence the term linear enamel hypoplasia (LEH). The ease with which LEH defects are observed contributes to its prominence in bioarchaeology research. Multiple LEHs may occur on a single tooth crown indicating repeated stress episodes during childhood when tooth formation occurred. Because the timing of tooth enamel formation is known, the location of LEH defects on the tooth crown allows an estimate of the individual's age at the time stress occurred, as well as stress duration and severity. Extensive studies of LEH in skeletal samples show that stress is more frequent and repetitive in farmers (versus foragers), slaves and poor-house samples (versus free and independent samples), low-status groups (versus middle and high status), rural (versus urban), and famine survivors (versus pre- or post-famine groups). Evidence of sex differences in frequency and level of stress is less conclusive, even in groups actively practicing son preference and daughter neglect. The biological buffering of female development

may explain this as a mechanism for protecting women's reproductive function. Larsen (2015, 52–57) provides an extended discussion of stress histories in human populations.

Pathological lesions

Three dental diseases—caries, AMTL, and periodontal disease—are often used in bioarchaeology (see BIOARCHAEOLOGY) to reconstruct diet and oral health in past populations (though other scientific methods of dietary inference are used—see DIET AND CARBON ISOTOPES; DIET AND SULFUR ISOTOPES; and FOOD RESIDUE ANALYSIS). The expression and frequency of these lesions in individuals and in past populations are interdependent and impacted by variables including dental wear and irregularities in the outer enamel surface due to EH and crown morphology. For example, two ancient Native American groups—one hunter-gatherer, the other horticultural—had different food processing technologies (wooden mortar and pestle versus sandstone *mano* and *metate*), causing differences in dental wear. The differences in subsistence method, food consumed, and food processing techniques resulted in clear differences in dental caries prevalence. Expanding on this example, the definition, diagnosis, and expression of three pathological dental lesions are documented (see DIFFERENTIAL DIAGNOSIS), then two comparisons are presented: first, an example of how oral diseases interact and exhibit different etiological pathways in foragers and farmers, and second, a summary of biological factors causing sex differences in dental caries and resulting in poorer oral health of women.

Dental caries

Dental caries is a disease process involving progressive, demineralization of dental hard tissues by organic acids derived from bacterial fermentation of dietary carbohydrates, especially refined sugars (Larsen 2015; Lukacs 2012). Diagnosis of dental caries in archaeological samples is different from caries detection in clinical samples. In bioarchaeology, dental caries lesions are routinely diagnosed as focal areas of cavitation in enamel

and dentine (Hillson 2001). In clinical research on living groups, dental caries is a dynamic process of demineralization and remineralization which produces a “white spot” or subsurface demineralization that precedes cavitation. This difference in caries diagnosis makes direct comparison of caries rates between past and present populations problematic. In ancient samples, vigilance is essential in distinguishing postmortem destruction of the tooth crown and root from cavitation due to cariogenesis.

Antemortem tooth loss (AMTL)

Loss of teeth during life is recognized by progressive resorption of the alveolus, a condition that may result from periodontal disease, penetrating caries, severe occlusal wear, or trauma (Lukacs 2012). Regardless of cause, once a tooth is lost, osteoclasts begin the process of resorbing alveolar bone, resulting in the progressive elimination of the alveolus. Alveolar resorption is quite variable but proceeds rapidly in the first years following tooth loss, then more slowly until the alveolus is obliterated. The cause of AMTL cannot be determined from a resorbed alveolus, though potential causes may be identified by observing the presence and patterns of associated dental attributes (degree of tooth wear) and pathological lesions (caries, periodontal disease).

Periodontal disease (periodontitis)

Inflammation and destruction of periodontal tissues anchoring the tooth to the jaw is referred to as periodontal disease. This condition results from the accumulation of bacterial plaque at the gingiva and causes reduction in height of the alveolar crest (Ogden 2008). Periodontal disease is often divided into two general categories: gingivitis and periodontitis. Only periodontitis is recognizable in skeletal specimens, by destruction of the tooth's connective tissue attachment and the loss of alveolar bone (Wasterlain, Cunha, and Hillson 2011). Periodontal disease is multifactorial, but in the absence of plaque it will not occur. Calculus, diet, and oral hygiene influence the onset and progression of periodontal disease. In dry bone it is difficult to distinguish remodeling due to

Figure 1 (a and b) Repetitive linear enamel hypoplasia, Chalcolithic Mehrgarh (4500 BCE): (a) MR 2: 60 (adolescent) two prominent LEH in central incisor and canine teeth; (b) MR 2: 34 (adolescent) four independent LEH visible on the lower left canine. Fewer events are visible on the lateral incisor and premolar teeth. (c and d) Pathological dental lesions in specimens with different modes of subsistence: (c) hunter-forager (Damdama) with AMTL of left molar teeth and pulp exposure visible in four teeth (RC, RP3, RM1, LC) due to severe dental wear; (d) farmer (Harappa) with slight dental wear, extensive AMTL (left molar row, P3, C; RM1), and pulp exposure due to penetrating caries in four teeth (RC, RI2, LI1, LI2).

periodontal disease from remodeling due to tooth wear, occlusal force, and continuous eruption.

Subsistence

Subsistence (food acquisition), diet (food ingested), and nutrition (adequacy of diet to support growth and health) are closely related components of a population's success and vitality. Important differences have been consistently observed in the oral health of foragers (or hunter-gatherers) versus farmers (agriculturalists). In this comparison, contrasting patterns of oral health are documented for two South

Asian groups. One is an aceramic, microlithic, seminomadic hunting-foraging group in the Gangetic Plain of north-central India (Damdama, 8800–8600 BCE; Lukacs and Pal 2016). The second is a sedentary, urban, Bronze Age farming group of the Indus Valley Civilization (Harappa, 2550–2030 BCE). Distinctive oral health differences between these two groups are exhibited in degree of tooth wear, caries prevalence, periodontal disease, and the cause of AMTL. In foragers the prime cause of AMTL is severe occlusal wear, while in farmers severe dental caries is the main cause. These differences are illustrated in the maxillary dental arcades of a Mesolithic forager from Damdama (Figure 1c) and a Bronze Age farmer from Harappa (Figure 1d). Note

differences in size of the maxilla, size of the teeth, severe degree of wear, pulp exposure, and AMTL in the Mesolithic forager, and numerous carious teeth, caries-induced pulp exposure, slight degree of wear, and AMTL in the Bronze Age farmer.

Sex differences

Sex differences in oral health are a common finding in the oral epidemiology of living populations and in the dental pathology profiles of past populations. Anthropologists typically explain poorer oral health in women (e.g., higher prevalence of AMTL and caries than men) as the result of sex differences in diet and behavior (Lukacs 2017). Since women prepare and cook food in most societies, they are closer to food supplies and have greater opportunity to snack and test foods during the cooking process than men. In addition to diet and behavior, physiological and hormonal differences between the sexes have been shown to influence susceptibility to caries and other dental diseases. Literature reviews reveal a pervasive and ubiquitous tendency for females to have higher rates of dental caries and AMTL than men—a trend seen in different societies, geoclimatic zones, and time periods.

Global data from epidemiological surveys of living groups show that during childhood males have significantly higher caries prevalence than females, or there is no intersex difference (Lukacs 2017). Yet among young adults, females have higher caries prevalence than males. This transition in oral health is likely due to the onset of puberty and menstrual cycling in women. These hormonal changes alter oral ecology in ways that promote cariogenesis. This shift is accompanied by accentuation of the sex bias toward poorer oral health (higher caries rates) during a female's reproductive years. Menstrual cycling and pregnancy cause biochemical changes that reduce saliva flow and alter saliva biochemistry, making the oral environment less antimicrobial and less able to buffer acid challenges that accompany ingestion of food. The increase in caries with agriculture is typically attributed to the change in subsistence and diet. However, the increase in fertility with the adoption of agriculture may be as important in explaining the decline in women's oral health as the difference in diet.

These ideas represent a significant change in the anthropological perspective on sex differences of oral health because greater recognition is now given to women's sex hormones and the cumulative effect of women's reproductive biology (menses and pregnancy) throughout the life course. The shift in perspective on the complexity of factors impacting women's oral health is clearly evident (see Larsen 1997, 72–76; 2015, 73–77). The study of oral health in past populations enhances our understanding of the intricate interaction of biology and behavior in human prehistory.

Osteology

CASSADY YODER URISTA

Radford University, USA

At its most basic, osteology is the study of bone. More specifically it is the scientific study of the structure and function of the skeleton. The analysis of the skeleton can be employed in a variety of contexts and disciplines, from human osteology, often examined by anthropologists and human anatomists, to faunal bone studied by zoologists, zooarchaeologists (see ZOOARCHAEOLOGY), and paleontologists. The study of skeletal material is fundamental to these disciplines because of the information that can be gleaned from it and its durability. In archaeological and paleontological contexts, the skeleton is often the only record left of the once-living animal. It can provide information on the structure of the body that can then be informative on its function. Skeletal structures are not static during life; they are instead molded by the activities of the living creature. In this way, the skeleton can help the osteologist reconstruct what the living creature was like: its diet, its health, how it moved around the landscape, its biological sex, age-at-death, and so on. Skeletal structures also reflect the evolutionary history of the animal and can be used to determine evolutionary relationships between different taxa.

Human osteology is the study of the human skeleton and is fundamental to much of the work of biological anthropologists. It is the cornerstone of human skeletal biology and paleoanthropology. Two of the major areas in human skeletal biology are bioarchaeology (see BIOARCHAEOLOGY) and forensic anthropology. Osteology is critical to these areas as it helps these practitioners determine as much as possible about the recovered human skeletal material including:

- age-at-death (see ESTIMATING ADULT AGE: AURICULAR SURFACE MORPHOLOGY; ESTIMATING ADULT AGE: PUBIC MORPHOLOGY;

ESTIMATING ADULT AGE: TRANSITION ANALYSIS; ESTIMATING SUBADULT AGE: DENTAL DEVELOPMENT AND ERUPTION; ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH; and ESTIMATING SUBADULT AGE: EPIPHYSEAL UNION)

- sex (see ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY and ESTIMATING SKELETAL SEX: METRICS)
- ancestry (see BIOLOGICAL DISTANCE)
- stature (see STATURE ESTIMATION)
- health (see ORAL HEALTH and PALEOPATHOLOGY)
- diet (see HUMAN SKELETAL GEOCHEMISTRY and MALNUTRITION)
- activity and trauma (see MUSCULOSKELETAL STRESS MARKERS and TRAUMA)
- perimortem events.

This information may help identify the individual, or what happened to them (forensic anthropology), or be aggregated with similar information from other skeletonized individuals to gain a population-level understanding about an ancient society (bioarchaeology). In paleoanthropological contexts, osteology is used to determine if the recovered fossilized bone is from a hominin, and if so what that bone might suggest about which of the hominin taxa it belongs to. Paleoanthropologists can then use their analysis of the skeleton to try to reconstruct, as much as possible, the sex, age-at-death, and stature of the fossilized individual. Aspects of daily life, such as diet and health, may also be revealed through osteological analysis of the fossil material. This information may help give a greater understanding about the extinct species.

Human osteological research has historically dominated biological anthropology, a trend that continues to this day. From its onset, osteological research has been highly descriptive. While descriptive research still dominates much of the reported osteological research, there has been a significant increase in analytical research, with an emphasis on hypothesis testing (Hens and Godde 2008). The earliest research in osteology

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0428

was focused on understanding human variation to aid in defining the race concept in humans (Armélagos, Carlson, and Van Gerven 1982). While understanding the nature of variation is still of significant importance in the field, much of the current research in this area is instead focused on methods to accurately assess basic demographic information such as age-at-death, sex, and ancestry for forensic and archaeological applications (see PALEODEMOGRAPHY) instead of for hierarchical racial classifications (Hens and Godde 2008; Stojanowski and Buikstra 2005).

Osteological analysis is often done at the macroscopic level. This involves visual inspection of the bone and comparisons with known element collections, especially for highly fragmented materials. Measurements can be taken to help in estimations of age, sex, ancestry, and stature (see DENTAL METRICS). In fact, among the earliest research in osteology was the metric analysis of human morphological variation to understand the origin and extent of human racial variation. Microscopic or histological examination of bone can be used in assessments of age-at-death and health. Bone chemistry and DNA analysis are also increasingly performed to aid in the identification of the individual (see DNA: MITOCHONDRIAL; DNA: NEXT GENERATION SEQUENCING; GENETICS: ANCIENT; and GENOMICS: ANCIENT), as well as in reconstructions of diet and migration in the past (see DIET AND CARBON ISOTOPES; DIET AND NITROGEN ISOTOPES; DIET AND SULFUR ISOTOPES; DIET AND TRACE ELEMENTS; MOBILITY AND LEAD ISOTOPES; MOBILITY AND OXYGEN ISOTOPES; and MOBILITY AND STRONTIUM ISOTOPES).

Faunal bone may be studied by zooarchaeologists, zoologists, and paleontologists. For anthropological questions, much of the relevance of faunal analysis relates back to questions about ourselves, in particular what the fauna might tell us about the environment and activities of the humans that lived contemporaneously. The analysis of faunal bone can determine the taxon and element of the bone. This might

give information from the kinds of species that shared the landscape with a fossil hominin to what was on the menu for an ancient group (see ZOOARCHAEOLOGY AND HUMAN DIET RECONSTRUCTION) or how that group moved across the landscape (see ZOOARCHAEOLOGY AND HUMAN TRADE AND MIGRATION).

Paleodemography

RICHARD R. PAINE

University of Utah, USA

Demography is the study of population over time and space. Demographers describe, statistically, the size, density, and distribution of populations across space, and rates of fertility, mortality, migration, and population growth (or decline) across time. Paleodemography attempts to provide similar description of ancient populations using data from human skeletons. An important characteristic of paleodemography has been its focus on cultural, ecological, and behavioral processes and their impact on ancient demographic patterns and community health. Though there are many examples of ancient health studies, understanding community health has proven an elusive goal. Reconstructing the demography of ancient populations is essential to the testing of evolutionary theories of human behavior, resource intensification, cultural evolution, and ecological degradation.

Paleodemography grew in the 1960s and 1970s as evolutionary and ecological approaches to human behavior were at the forefront of anthropological archaeology. J. Lawrence Angel outlined the goals and promise of paleodemography in his (1969) article “The Bases of Paleodemography” as follows: to reconstruct the “population picture” of an ancient settlement including age composition, age-specific mortality, adult longevity, and sex ratio, and “if possible” fertility and rates of natural increase. During the 1960s and 1970s, paleodemography focused on relationships between human health and demography and culture change, especially the consequences of the adoption of agriculture as exemplified by syntheses of culture change and mortality (e.g., Acsádi and Nemeskeri 1970). These early studies focused on changes in human mortality through the construction of life tables from excavated skeletal collections,

and on the use of skeletal lesion frequencies as indicators of prehistoric health conditions. Paleodemographic life tables depend on two critical assumptions: first, that the population that produced the skeletal sample was stable, that its fertility and mortality rates were constant over an extended (<100 years) period; and second, that the population was stationary, neither growing nor declining. A major conclusion of these early studies, based on declines in the mean age at death and increases in lesion frequency, was that the shift from foraging to farming brought significant negative consequences for human health.

Paleodemography began a period of thorough self-evaluation and self-critique in the 1980s. Three critical analyses dragged paleodemography out of its childhood. First, Bocquet-Appel and Masset's (1982) “Farewell to Paleodemography” identified the “reference sample” problem as a critical source of bias in age at death estimates. Second, Sattenspiel and Harpending (1983) demonstrated that fertility and population growth, rather than mortality, were the primary determinants of the mean age at death (MAD) and the overall age distribution of death in a given population. MAD had been broadly used as a proxy for life expectancy at birth. This recognition had profound implications for previous studies, which had, based on life tables, identified declines in “life expectancy” following the adoption of agriculture as evidence that agriculture had been detrimental to human health. Following Sattenspiel and Harpending, declines in mean age at death are primarily evidence of increased fertility and population growth. Third, Wood and colleagues (1992) introduced the concepts of heterogeneous frailty, hidden heterogeneity, and selective mortality to paleodemography. The “osteological paradox” called into question basic assumptions about the relationship between lesion frequencies and ancient health conditions. This tradition of disciplinary self-critique has led

to ongoing efforts to remove bias from skeletal aging techniques (Hoppa and Vaupel 2002), and to better understand the relationship between cemetery samples and living populations (e.g., DeWitte and Wood 2008; Paine 2000).

The data of paleodemography are archaeologically recovered human skeletons. Paleodemography employs morphological markers associated with age and sex and skeletal lesions associated with malnutrition or pathology to reconstruct basic demographic rates and patterns. As the human body develops and matures, it goes through a series of predictable morphological changes associated with growth. These include the formation and eruption of teeth and the gradual closure of skeletal epiphyses. The adult ages are also linked to morphological changes in the skeleton. These include changes in the major joints of the pelvis (the pubic symphysis and iliac auricular surface) and the sutures of the cranium. Because developmental changes in skeletal morphology are fairly consistent, where the morphological changes associated with estimation of adult age are heavily influenced by individual health conditions, age estimates become less precise and interobserver differences in age estimates increase as actual age increases.

Commonly used sex markers in the skeleton do not appear until individuals reach full reproductive age. Therefore, it has been generally considered to be impossible to estimate sex for subadults, though osteologists continue to seek new markers, including features of subadult mandibles and eye orbits. Several experimental studies have attempted to determine the sex of subadults using DNA recovered from excavated skeletons. These methods have focused on the amelogenin gene, which varies in size between the X and Y chromosomes, and on genes located on one of the sex chromosomes, usually the Y. Because ancient DNA recovery is both expensive and destructive, these techniques are not yet practical on a large scale.

Preservation may have strong effects on age and sex estimates from excavated skeletal series, including methods that employ ancient DNA. Preservation conditions vary from site to site and even between adjacent graves. Some morphological features are more commonly preserved than others; within the same skeletal series,

morphological markers available to estimate age and sex may vary between individual skeletons.

Reference sample bias

Bocquet-Appel and Masset (1982) were the first to draw attention to statistical biases resulting from the use of reference samples. They showed the statistical tendency of studied series to be drawn toward the reference samples. Reference samples, like the Hamann-Todd collection, are collections of skeletons associated with a documented age at death. They are used to describe morphological changes in the skeleton that come with age. Unfortunately, these collections tend to have unique age and sex distributions reflecting their source populations. For example, the Hamann-Todd collection, housed at the Cleveland Museum of Natural History, the United States, is made up of unclaimed individuals from Cleveland area hospitals and the Cuyahoga County morgue. The collection skews toward men, especially adult men from precarious economic situations. This type of bias is typical of known-age collections. The range of variation in morphological change correlated with age is captured more fully in overrepresented age and sex subgroups and less fully in age and sex subgroups that are not so well represented. Any morphological aging method that is based on observations of a reference sample will cause age estimates to be drawn toward those overrepresented categories (Bocquet-Appel and Masset 1982; Hoppa and Vaupel 2002). Several authors (e.g., Hoppa and Vaupel 2002) have developed methods to produce age estimates which are not affected by reference sample bias. These methods apply an informative prior distribution (an estimate of the likely age at death distribution for the study population) and Bayes' theorem to unknown skeletal samples. Though mathematically complicated, these methods have proven successful. Today, paleodemographers have the choice to employ unbiased methods, including Boldsen and colleagues' (2002) transition analysis (see ESTIMATING ADULT AGE: TRANSITION ANALYSIS), and increasingly are doing so.

Heterogeneous frailty/hidden heterogeneity

Every individual in a population has a unique ability to resist death, referred to as their frailty. This heterogeneity of frailty is based on many factors including age, sex, genetics, local environmental conditions, socioeconomic status, and diet. Over time, there has been an important shift in emphasis away from viewing heterogeneity as a hindrance to research, toward making it a focus of paleodemographic study. This has been particularly important in studies of complex societies where archaeology can supply evidence of heterogeneity in socioeconomic conditions, for example. In the future, presently hidden heterogeneity like childhood nutritional patterns may become the focus of frailty studies as isotope and elemental studies of tooth enamel become practical and affordable.

Selective mortality

In his pioneering work, Angel (1969) pointed out that lesion frequencies in skeletal series are not direct reflections of frequencies in a living population. They represent only the subset of individuals who died at any given age. Mortality is not random; it is selective. On some levels, those who are most frail will have higher mortality than those who are less frail. Therefore, skeletons, regardless of age, represent the frailest members of a population. For example, the 20-year-old in a skeletal series is not representative of 20-year-olds from the living population, most of whom would be expected to live many more years; the former represents the rare 20-year-old who died. This has important implications for studies that attempt to assess ancient community health using lesion frequencies.

Since the 1980s, many studies have attempted to examine, explicitly, the links between ancient health conditions and effects and their outcomes in skeletal series. Two approaches have characterized these attempts. The first is the use of hazards analysis to explore the relationship between skeletal markers (e.g., height, the presence of lesions), heterogeneous frailty, and mortality. DeWitte and Wood's hazards analyses of Black Death cemeteries in England (DeWitte and Wood 2008) are an excellent example of such

work. They explore selectivity in plague mortality using height and nonspecific lesions as proxies for frailty. The second is the use of population models to simulate the effect of demographic events on skeletal age distributions. Paine's (2000) examinations of the outcomes of epidemic events are an example of modeling population processes to understand their impacts of skeletal age distributions. After three decades of intense self-critique and theoretical and methodological advancement, paleodemography has a better overall understanding of its data, their limitations and potential, than most areas of ancient studies.

Paleodemography and Hazards Analysis

SHARON N. DEWITTE

University of South Carolina, USA

Hazards analysis is a potentially powerful way to derive paleodemographic information (see PALEODEMOGRAPHY) from skeletal samples, which are often relatively small and plagued by problems of missing data resulting from various selection processes such as selective mortality, preservation bias, systematic variation in burial practices or locations, and incomplete excavation (Milner, Wood, and Boldsen 2008). Hazards analysis provides an alternative approach to paleodemographic life table estimation (see LIFE TABLE ANALYSIS) (Konigsberg and Frankenberg 2013; Wood et al. 2002). Hazard models specify the time until a certain event occurs, such as death in the case of skeletal samples. Hazards analysis often involves using skeletal data to estimate the parameters of a mortality function, survivorship function, or age-at-death distribution (all of which are related equations). Models with few parameters can be applied to small samples, and they smooth the random variation in mortality data that is an artifact of small samples, without imposing any particular age pattern on the data. Hazard models also accommodate missing data, which is important given the incomplete nature of many skeletal samples and when, as is often the case, bioarchaeologists use age estimation methods that do not provide good estimates for older adults ages (i.e., many methods yield broad terminal age-intervals; however, see ESTIMATING ADULT AGE: TRANSITION ANALYSIS).

Examples of useful parametric models are the Gompertz, Gompertz–Makeham, and Siler models (Wood et al. 2002). The Gompertz mortality function describes the senescent pattern that is typical of human populations: Mortality is relatively low at early adult ages and then increases rapidly at older ages. The mortality function has two parameters: One represents the

overall level of mortality due to aging, and the other represents the rate at which the force of mortality increases with advancing age. It is based on a model of aging that assumes physiological capacity declines with age as a negative exponential and that the risk of death is proportional to the amount of physiological capacity remaining to an individual (Gage 1989). This assumes a relatively simple relationship between physiological capacity and mortality, which might not always be true. More complex and thus perhaps more realistic models would require additional parameters, but increasing the number of model parameters increases the sample sizes required. Small samples typically require paleodemographers to choose models with few parameters that are therefore estimable, rather than models with many parameters that more closely reflect reality but require inaccessibly large samples.

The Gompertz–Makeham model includes a hazard (the Makeham component) that is constant across all ages; it is associated with exogenous causes, such as accidental deaths, that are independent of age or the physiological state of an individual. The Gompertz–Makeham model incorporates the idea of competing hazards or causes of death. There are multiple possible causes of death and they are independent of each other, so individuals who avoid one cause of death are subject to the remaining causes of death in the same manner as everyone else. Surviving the causes of death associated with the Makeham component has no effect on one's risk of death from causes associated with the Gompertz component. It can be difficult to estimate the Makeham component with small, incomplete samples (Herrmann and Konigsberg 2002).

The Siler model adds an immature component (a negative Gompertz function) to the Gompertz–Makeham model to reflect the common pattern of relatively high mortality at birth followed by a rapid decline during infancy and childhood. This component has two parameters: One represents the initial force of mortality associated with infant and childhood causes, and the other represents the rate at which

this declines with increasing age. A possible biological interpretation of this immature component is that mortality is proportional to the likelihood of infection and inversely proportional to the level of immune competence, so as children get older, their immune competence improves and the likelihood of infection, and death thereof, declines. The three components of the Siler model combined approximate the roughly U-shaped curve of mortality observed in human populations.

Hazard models can be fit to age-specific survivorship rates, the force of mortality, or the age structure (the probability density function (PDF) of ages at death) (Gage 1988). It is best to fit the survivorship function when the data are likely to be accurate, as this does not require assumptions about the stability or stationarity of the population. However, if the data are defective (as is typical of paleodemographic data), it is better to fit the force of mortality or age structure.

In addition to these fully parametric models, paleodemographers have applied semiparametric and nonparametric approaches to assessing survival and mortality. For example, the Cox proportional hazards model is a semiparametric model that allows for the estimation of the risk of death and of the effects of variables (e.g., sex, urban versus rural, high versus low status) on that risk. It does not, however, require the specification of a baseline hazard of mortality, and so parameters for a hazard function are not estimated. Survivorship and variation thereof within or between populations can also be assessed nonparametrically using Kaplan–Meier survival analysis. These approaches can be applied to

smaller samples than those required for fully parametric analyses.

Paleopathology

FRANCISCA ALVES CARDOSO

Universidade NOVA de Lisboa, Portugal

Paleopathology is viewed as an interdisciplinary and multidimensional discipline that focuses on the study of health conditions of past individuals and populations, aims to trace the origin and evolution of diseases, and reconstructs individuals' and populations' health profiles (Ortner 2003). Its goals are holistic and imply biocultural interpretations of disease. Therefore, to allow an accurate understanding of the past, and assess the impact diseases would have had, contextualizing all information used in paleopathological analysis is in order. Thus, it is not sufficient to understand signs and symptoms of disease in current living populations—used as proxies—to think about the past. In paleopathological studies, cultural and social interpretation of signs and symptoms of a disease need to be contextualized. This is relevant since a cultural filter may impact the manner by which the concept of “disease”, or being “ill,” is lived by the affected individual and perceived by the population at large.

This growing sensitivity to context in paleopathological cases reflects the changing body of scholars involved and trained in the discipline. Earlier scholars had mostly a medical training, with studies focusing on individual skeletons or mummies, such as case studies and osteobiographies. Scholars from the second half of the twentieth century onwards have a more diversified academic background, with an emphasis on social sciences and humanities such as anthropology and archaeology. Nevertheless, paleopathology continues to be associated with many diverse academic departments (e.g., anthropology, archaeology, anatomy, pathology, radiology, and any other fields related with medical sciences, including forensics), and each scholar will inevitably associate paleopathology with his/her theoretical and academic background. In this text, the term paleopathology—and

paleopathologists—will be used in reference to those that study evidence of disease in the past via analysis of human bone, tissues, and teeth.

Paleopathology has progressed scientifically since its early onset. Charlotte Roberts and Jane Buikstra's edited volume *The Global History of Paleopathology: Pioneers and Prospects* (2012) offers an overview of the history of paleopathology, outlining the practice of paleopathology in various regions of the globe and allowing for a first-hand expression of the many scholars who are actively engaged in the discipline worldwide.

Paleopathology uses human skeletons and/or commingled bones and teeth as primary sources of data. Skeletal remains contain a great amount of information regarding an individual's ancestry, behavior, and disease. Evidence of disease in human remains is as old as human evolutionary history itself. The diagnosis that Lucy, a 3.18-million-year-old *Australopithecus afarensis*, had suffered a traumatic injury is illustrative of the case. Most of the human remains studied in paleopathology are far more recent than Lucy's 3 million years of age. Nevertheless, the chronology ranges from the Paleolithic (10,500–8000 BCE) to contemporary human remains. An example of this impressive overarching chronology is the project *A History of Health in Europe over the Past 10,000 Years* (<https://www.dur.ac.uk/research/directory/view/?mode=project&id=402>).

The goals of paleopathology are varied, reflecting the discipline's interdisciplinary and multidimensional scope, ranging from the simple macroscopic observation of bone and teeth changes aiming to diagnose a disease in an individual, to the reconstruction of long-term trends and patterns of disease in populations: all while exploring disease association with biological and social inequalities, and how these may relate to sex, age, work, and ultimately disease itself. With the development of ancient DNA analysis (see GENETICS: ANCIENT), and other biochemical and biomolecular techniques, paleopathology expanded its aims to the understanding of disease at a microscopic and evolutionary level. New

insights into population migration (see MOBILITY AND LEAD ISOTOPES) and how it may relate to population genetics, and both of the previous with pathogens, have favored exploring the coevolution of humans and pathogenic organisms.

In addition to skeletons, some paleopathological cases consist of mummies (e.g., Egypt), or bodies in peat bogs (e.g., bog bodies in Denmark), as certain environments and/or body manipulation techniques preserve more than bones and teeth. These remains offer complementary information to that observed in bones, since soft tissue can be analyzed. Preserved feces (coprolites) (see COPROLITES) have also yielded important information on agents associated with diseases. Some studies have been successful in recovering and identifying preserved eggs of parasites, such as roundworm and whipworm (see PARASITOLOGY). Additionally, secondary sources of information, such as paintings, religious statuary, pottery, burial goods, and written documents are important in paleopathology (Buikstra and Beck 2006; Grauer 2012; Ortner 2003).

The rationale behind paleopathological analysis is simple: It assumes that abnormal bone changes have a pathological nature, if not caused by deterioration after death and burial. Tissue deterioration will have a negative impact in paleopathology as it may cause a difficulty for, and even prevent, any type of analysis. Therefore, before addressing pathological bone changes, postmortem bone changes need to be evaluated when undertaking a paleopathological study. Taphonomy (see TAPHONOMY) is the study of such postmortem changes, and includes multiple factors that act upon a body after its death and until it has been environmentally recycled. The reference to taphonomic changes includes all postmortem abnormal modifications observed in bone and teeth that are the result of either the immediate burial environment and/or problems during or after excavation. These postmortem changes are also known as pseudopathological, since it is often difficult to macroscopically differentiate between both pathological and taphonomic changes, particularly when remains are poorly preserved or modified. Bone changes resulting from burial practices such as cremation exemplify the latter. Bone and teeth exposure to heat will fragment and modify their shape and form, and color, challenging an accurate

assessment of any changes of pathological nature. However, this burial practice offers insights into a community's social and cultural behavior.

Paleopathological analysis starts with an assessment of the remains biological profile. This includes the assessment of sex and age at death (see ESTIMATING ADULT AGE: AURICULAR SURFACE MORPHOLOGY; ESTIMATING ADULT AGE: PUBIC MORPHOLOGY; ESTIMATING ADULT AGE: TRANSITION ANALYSIS; ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY; ESTIMATING SKELETAL SEX: METRICS; ESTIMATING SUBADULT AGE: DIAPHYSEAL LENGTH; and ESTIMATING SUBADULT AGE: EPIPHYSEAL UNION). When addressing commingled human remains, that is, disarticulated remains, these two biological parameters may be extremely difficult to infer, although not impossible. The skeleton is also assessed for anatomical variation. This includes bone measurements and assessments of shape and form, aiming to calculate stature and morphological parameters such as robusticity. In addition, nonpathological variations are assessed, including discrete traits (see DISCRETE TRAITS), also known as epigenetic traits, which are considered nonpathological but expressions of an individual's uniqueness. This recording is the basis of paleopathological studies: it is very important to understand the wide range of anatomical variation, as well as taphonomic or disease-related changes. After establishing the biological profile, all bone changes are recorded. Standardized recording protocols are mandatory so that reliable and objective data can be collected, allowing future comparisons between populations and ensuring the accurate characterization of bone change and diagnostic criteria of pathologies (Buikstra and Ubelaker 1994). Ideally, recording bone changes should use unambiguous terminology, precise identifications of the location and distribution of bone changes, and descriptive summaries of the morphology of the change.

Detailed description of the location and type of changes is essential in paleopathology, as bone tends to react to stress in very similar manners, exhibiting either remodeling or destruction of bone tissue, or both. Thus, often the location, distribution, and pattern of changes are essential to perform a diagnosis. For example, infectious diseases such as tuberculosis preferentially affect the ribs and spine, with preference for the thoracic

vertebrae, while changes in the bones of the face, hands, and feet are more likely to be related to leprosy (Ortner 2003). Fortunately, even when assessing damaged and incomplete skeletons, pathological diagnoses, as well as the exercise of differential diagnosis (see DIFFERENTIAL DIAGNOSIS), are still possible as certain diseases have pathognomonic traits, that is, disease-specific bone changes. For example, eburnation (polishing) of articular surfaces is pathognomonic of osteoarthritis, and a flowing ossification along the anterolateral body of thoracic vertebrae is a criterion used to positively discriminate diffuse idiopathic skeletal hyperostosis (DISH), also known in the medical literature as Forestier's disease. In the absence of pathognomonic traits one may still allocate particular bone changes to specific disease categories such as trauma (see TRAUMA), development or congenital diseases (see CONGENITAL CONDITIONS), metabolic (see METABOLIC DISEASE) and endocrine diseases, tumors or neoplastic conditions (see CANCER), infectious diseases (see INFECTIOUS DISEASE), joint diseases (see DEGENERATIVE JOINT DISEASE), oral diseases (see ORAL HEALTH), nonspecific infectious diseases, and others that tend to fall into a category of miscellaneous conditions (Ortner 2003; Grauer 2012).

Paleopathology addresses both individual cases (e.g., osteobiographies) and population studies that are essentially hypothesis driven. In both, the methods of recording changes are the same, and involve recording all that is non-normal bone change. However, in population studies, the recording of non-normal changes may target specific bone changes and/or anatomical locations aiming to explore and study a specific pathological condition. For example, to assess degenerative joint diseases (DJD), researchers focus on the articular surfaces and record the known DJD—porosity, eburnation, and marginal and surface osteophytes (Buikstra and Ubelaker 1994, 115). The end result is a disease-specific population study. Exclusion of cases that may bias the presence of DJD (or pathology under study) is mandatory. Also, it is extremely important to consider the context. When studying a population with a high frequency of DJD, researchers need to consider confounding factors that may bias the results, such as age, sex, living conditions, occupation, and activity patterns.

Paleopathological bone changes are primarily observed with the naked eye, or in some cases with the aid of a binocular microscope. However, with growing awareness of the complexity of bone tissues' response to stress, and the relevance of taphonomy, complementary methods of analysis have been increasingly used, including imaging techniques such as radiography, computerized tomography (see COMPUTED TOMOGRAPHY), and 3D laser scanning (see LASER SCANNING). These allow for a nondestructive approach to studying bone changes. Unfortunately these techniques are not accessible to all paleopathologists. Histological analysis of bone tissues (paleohistology) and ancient DNA analysis (paleogenetics) are also used. Paleogenetics has permitted the positive identification of pathogens responsible for a series of diseases such as tuberculosis, leprosy, and syphilis, opening new research avenues and hypothesis-driven studies in paleopathology. The same applies to paleohistology, which uses histological techniques on bones recovered from archaeological sites. Paleohistology deepens the understanding of bone tissue morphology and shows stages of cellular activity, such as excessive tissue mineralization and signs of abnormal bone reabsorption associated with past diseases. Paleohistology is also highly important in cases aiming to differentiate between antemortem and postmortem bone changes to facilitate differential diagnosis. However, despite the magnificent insights these techniques offer, they require both the destruction of bone and tooth samples, and resources and facilities that are not available to all paleopathologists.

Paleopathology has come a long way from its onset; however, limitations still exist. The accuracy of diagnoses obtained from skeletal evidence and the subsequent interpretation and use to reconstruct the health and behavior of past populations are recurring concerns (Wood et al. 1992). The fact is that many diseases do not leave evidence on the skeleton. Only a small percentage will leave such evidence, depending on a person's (i.e., organism and immune system) capacity to survive stress. Observing disease-related bone changes in skeletons means that the person coped with the condition, but does not necessarily inform about cause of death. Alternatively, it has been acknowledged that the absence of disease-related bone changes does

not equate absence of disease: A person may have had a disease that left no evidence on their bones. Furthermore, poor preservation and/or absence of remains prevents detailed recording of changes, and accurate frequency estimations and methods continue to be subjective as scholars adapt recording protocols to accommodate research questions and fragmentation of the remains. Moreover, paleopathology continues to rely heavily on gross macroscopic observation, contrasting with the few diseases that are credited to leave pathognomonic traits on bones. Paleopathology will continue its development as new techniques and approaches to bone changes are explored and improved.

Parasitology

KARL J. REINHARD

University of Nebraska–Lincoln, USA

Introduction

Archaeoparasitology is the science that focuses on the relationships between parasite biology, human behavior, and environment that defined past infection patterns. It depends on archaeological information regarding subsistence, medicines, demographics, sanitation, environment, trade, and many other lines of archaeological investigation. It also depends on the understanding of complex parasite life cycles and principles of parasite ecology. In multisite analyses, archaeoparasitology defines various correlations of parasitism associated with the development of complex societies and changes in subsistence. It sheds light on the health impact of urbanization and empire expansion. When tightly applied to a single burial or mummy, archaeoparasitology shows how habits promote infections and disease on an individual basis (Reinhard and Araújo 2016). Latrines, coprolites, and mummies are sources of direct diagnoses. Especially in the Americas, coprolites and mummies provide epidemiological data sources.

Archaeoparasitology has entered a new age of population studies using a spectrum of analytical methods. Molecular biology (aDNA analysis), immunological tests (enzyme-linked immunosorbent assay (ELISA)), scalp examination for lice, and microscopic analysis of sediments are methods for identifying parasites. In addition, gross pathology exhibited in human remains can be used to infer parasitism.

An axiom in parasitology is that a minority of hosts carries the majority of parasites. This is known as the negative binomial distribution. Several studies of both ectoparasites and endoparasites showed that the negative binomial is evident in archaeological series (Camacho et al. 2018). This is of crucial importance

because archaeoparasitology has equivalent epidemiological strength as modern surveys of living populations. Thus, archaeology can show infection patterns of past lifestyles, separated from the modern world by wholly different behavioral adaptations.

Archaeoparasitology entered a new period of diversifying concepts because the field of parasitology has generated a wealth of theoretical perspectives. Many of these can be used to generate hypotheses testable with archaeological data. Some of these, such as the application of the nidus concept, formed the underpinning for the new approach to understanding ancient infection risks. This emerging area is called pathoecology (Reinhard and Araújo 2014, 2016).

Pathoecology is an approach to ancient health assessment that is based on a reconstruction of infection from a variety of parasites evident in a population. For the infection component of pathoecology, the nidus concept of Pavlovsky is useful (Slepchenko and Reinhard 2018). Pavlovsky was a parasitologist who developed the model of any given parasite infection being dependent on the overlap of parasite and host in a geographical space that favors transmission. The nidus is this space. From the archaeoparasitological perspective, this space can be as finite as a room enclosing dog- and human-susceptible hosts that is infested with infected kissing bugs. Within this nidus, the nocturnal kissing bugs are the vector for the parasite *Trypanosoma cruzi* which can cause Chagas disease. In archaeological populations, several parasites are often found at the same site. Because the life cycles of the parasites are known, the overlapping nidi of several parasites can be deduced. Therefore, the nidi and risk behaviors of the populations can be inferred and compared (Reinhard and Araújo 2014, 2016).

When pathoecology is applied on a continental scale, larger comparisons of lifestyle can be made. Fecal-borne parasites were remarkably well controlled in the prehistoric Americas. In contrast, such parasites were ubiquitous in premodern Europe, west of central Russia. Fecal-borne parasites are evidenced by the durable eggs of *Ascaris*

lumbricoides and *Trichuris trichiura*. In Europe, the emergence of ubiquitous filth parasites was associated with population increase at the onset of agriculture. In contrast, filth parasites were rare in the Americas. The behaviors that defined these patterns were addressed by Reinhard and Pucu (2014). For Europe, behaviors that promoted infection included uncontrolled excrement disposal, use of feces as fertilizer, poor personal hygiene, and crowding. Also, the humoral concept, the basis of European medicine, did not recognize the germ theory. Evidence from the Americas suggests that a number of behaviors reduce exposure to feces. These included less crowded conditions, antihelminthic therapies, the establishment of sanitation, the perception of infection causality, agricultural practices that limited pathogen transmission, and the role of diet in the spontaneous clearance of worm infections (Reinhard and Pucu 2014). Therefore, from finite spaces in archaeological sites to large-scale comparisons, the nidus concept and pathoecology are very useful in understanding different trajectories of parasite–human associations.

The parasitological analysis of latrine features can provide the best evidence of parasite emergence and control related to sanitation. Trigg and colleagues (2017) synthesized data accumulated from New England historic sites by several researchers between 1986 and 2007. The data included analysis of 114 latrines from seven cities. The earliest samples date to 1650 and the latest to 1900. Socioeconomic information was overlaid on the archaeoparasitological data. Using this extensive dataset, the authors defined biological and cultural variables that shaped the pathoecology of developing cities. Control of fecal-transmitted parasites was gradually achieved, beginning with *T. trichiura* and eventually with *A. lumbricoides* by the end of the nineteenth century. Transmission and control were defined by changing microenvironments associated with urbanization, development of sanitation, and variable use of urban spaces. Poorer households were more susceptible to infection due to use of feces-contaminated yards for gardening. Also, the poor had a delayed access to sanitation. This study reflects the maturation of archaeoparasitology among historic archaeologists which is based on analysis of large data sources in cultural contexts.

Analysis of the distribution and genetic composition of parasites over long time periods and across large geographic ranges provides insight into evolution of parasites after host switching events. Reinhard and Araújo (2014) review the data for *T. cruzi*. For the last decades of the twentieth century, the conventional wisdom was that *T. cruzi* emerged as a human parasite in the Andes after sedentism developed and animal domestication was innovated. Dogs and guinea pigs are alternative hosts for *T. cruzi*. It was believed that once dogs, humans, and guinea pigs began to live in kissing-bug-infested domiciles, infection became common in humans. This process was called domiciliation. By 2003, evidence of infection predating animal domestication was discovered, as was evidence of *T. cruzi* well outside of the Andean geographic range. The application of molecular biology to large series of mummies revealed a different picture. There was a host switch to humans on the part of *T. cruzi* some 9,000 years ago. Later, molecular biologists were able to test for the six variants of *T. cruzi* DNA. The latter study was enlightening. The oldest infections were with wild strains of *T. cruzi* related to a bat strain and were possibly caused by oral ingestion of contaminated food. After agriculture and animal domestication, three domiciled strains infected Andean populations. Geographically, the analysis of *T. cruzi* strains in modern populations raised another question. Molecular biologists identified a peculiar *T. cruzi* DNA variant called TcIDOM. This variant is associated with a significant proportion of human infections in South America, yet is closely related to wild strains in North/Central America. The molecular biologists who made this discovery proposed that TcIDOM had an origin in North America in paleo times, and was then dispersed back into South America as domiciled cycles. They recognized some problems with this hypothesis. Hunter-gatherer population densities were not sufficiently large enough to support a sustained domestic cycle. To address this question, Reinhard and Araújo (2014) reviewed the archaeology of the Lower Pecos Canyonlands and showed that the archaic population was sufficiently large and sedentary to sustain transmission at least by 5,000 years ago. At the same time, earth oven cooking technology changed the landscape to enhance the wild cycle of the

parasites between rodents and kissing bugs. In addition, dietary preferences for the wild rodent hosts of *T. cruzi* resulted in kissing bugs infesting human sleeping areas. Therefore, *T. cruzi* could have undergone a *de facto* domiciliation among archaic peoples in North America. The culmination of decades of archaeoparasitology focused on *T. cruzi* completely changed the general consensus on the origins of Chagas disease. The original theory related to animal domestication was too simplistic. Intense molecular scrutiny on the topic revealed a more complex web of host switching events relating to six strains of the parasite and involving vector transmission through kissing bug feeding and also oral transmission.

Archaeoparasitology shows that parasites emerged and reemerged throughout time. An example is presented by Kuchta, Serrano-Martínez, and Scholz (2015) who describe the emerging health challenge of Pacific broad tapeworm (*Adenocephalus pacificus*) infection. This parasite normally infects sea lions. However, the final intermediate hosts, several species of fish, are eaten by dogs and humans. As a result, dogs and humans become infected in Peru and Chile. However, *A. pacificus* has a long pre-history of infection dating to 6,000 years ago (Kuchta et al. 2015). In archaic periods, infection prevalence fluctuated with climate conditions. Infection was variable after agriculture. Therefore, human and environmental conditions resulted in emergence, disappearance, and reemergence of infection.

Some infections result in calcifications that can be recovered in burial excavations. Kristjánssdóttir and Collins (2010) review the archaeological evidence of hydatid cyst disease and present several cases found in a medieval Icelandic hospital. The tapeworm *Echinococcus granulosus* provokes hydatid cyst disease in humans and animals. In humans, the liver and lungs are the most commonly affected, but cysts can form in other tissues as well. The cysts calcify and form resistant structures. Therefore, they can be found in skeleton context. In Iceland, the parasite cycled between dogs and sheep. Sheep were the intermediate host carrying cysts and dogs were the definitive host carrying egg-laying adults. The eggs, once ingested by humans, formed hydatid cysts. Kristjánssdóttir and Collins (2010) note that hydatidosis was a widespread endemic

health problem in Iceland which became the focus of a strict control campaign by the late 1800s. The severity of the problem was clearly evidenced in hydatid cysts recovered from a 1493–1554 monastic hospital cemetery. The cases were buried in close proximity to each other which suggests that hydatidosis was a recognized syndrome. The cases included the largest hydatid cyst known from archaeological context. All of the infected individuals were 50 years or older and six were over 60 years of age. The infection was equally divided between men and women. A total of 160 graves were excavated so that calcification of hydatid cysts was achieved in 5 percent of the population. This suggests that the infection did not cause much pathology in the people associated with the cysts. However, only 20–30 percent of hydatid cysts calcify and this suggests that the percentage of the population infected could have been as high as 25 percent. This study shows how careful excavation of a large population can provide insights into the establishment of a sustained domestic cycle involving dogs and sheep that resulted in human infection.

Korean remains from the same cemeteries show an absence of parasites with skeletonized burials and ubiquitous parasites in mummified burials (Seo et al. 2010). Korean researchers have focused their work on mummies and made remarkable discoveries concerning past distribution of parasite infections (Seo et al. 2014). They combined microscope and molecular diagnoses on Joseon Dynasty (fifteenth to nineteenth century) tombs, and diagnosed four species of food-borne helminths. All of these are trematodes, or flukes, which are parasitic flatworms. The fish-borne flukes include *Clonorchis sinensis* (Chinese liver fluke) and *Metagonimus yokogawai*, an intestinal fluke. One-third of the mummies were infected with one or both of these flukes. In the upper strata of Joseon society, uncooked fish was commonly eaten. Eating uncooked crab was the infection source of the lung fluke *Paragonimus westermani*, which was found in 20 percent of the mummies. Oysters were the source of the intestinal fluke *Gymnophalloides seoi*, infecting 10 percent of the mummies. In total, 61 percent of the Joseon mummies were infected with one or more species of fluke. When the nematode

(roundworm) data are added to the picture, all mummies were positive for one or more species: 56 percent contained eggs of *A. lumbricoides* and 72 percent were positive for *T. trichiura*. Therefore, fecal contamination of the human environment was a problem, since infection can be associated with unwashed food. Pinworm was found in 11 percent, which reflect airborne or person-to-person infection within habitations. A rare parasite, *Strongyloides stercoralis*, was found in two mummies. Infection occurs when larvae of these parasites burrow through the skin. Another unusual parasite, *Trichostrongylus*, was found. The larvae of this genus must be eaten to cause infection. These last two parasites were found together in a single mummy. The pathoecology reflected by these mummies is complex with nidi, including the water sources from which fish, oysters, and crabs were collected, the fields in which plants were grown (*Trichostrongylus*, *A. lumbricoides*, and *T. trichiura*), and even the enclosed structures in which the elite lived (pinworm).

This entry reflects the maturation of archaeoparasitology. In a foundation article, Reinhard (1992) predicted that parasitology would be a tool for the archaeologist. He specifically projected that parasite data would shed light on diet, transhumance, trade, environmental contaminants, health, interaction with domestic animals, and human-parasite ecology and evolution. Archaeoparasitology has made contributions in all of these areas. However, with molecular biology as a newer diagnostic tool, the field is making strides in showing evolution of parasites through time and geographical space.

Stature Estimation

BENJAMIN M. AUERBACH

The University of Tennessee, USA

The estimation of stature—the height of an individual—is used on human skeletal remains regularly within the contexts of paleoanthropology (see BIOARCHAEOLOGY) and forensic anthropology. While researchers have continued to refine methods, most involve the extrapolation of stature from limited, fragmentary skeletal remains. These reconstructions are used to understand the impact of lifeways on individuals, document changes in diet and environmental stress over time, and develop a measure against which to scale other individual biological dimensions. Herein, the history of stature estimation is briefly reviewed, followed by a summary of current methods and their applications.

A history of stature estimation methods

For over a century, researchers have successively refined the statistical methods for stature estimation, introducing new approaches and samples to address shortcomings noted in previous methods. One significant concern driving continued research on stature estimation is that, because human groups vary in the proportions of bone lengths to total stature, accurate estimation methods are often region- or group-specific. A mismatch between the reference sample used to create estimation equations and the group to which the equations are applied may result in incorrect stature estimations. As a result, many of the studies produced within recent years have focused on minimizing this incongruity, which was established a century ago.

Estimations of stature were formalized in a consistent and repeatable scientific methodology in the late nineteenth century. These earliest methods related the lengths of limb long bones to known statures for individuals directly, generally

using ratios. Étienne Rollet, a physician and anatomist who amassed osteometric data from cadavers, was the first to develop these methods in 1888, followed by Leonce Manouvrier and Thomas Dwight, both also physicians and anatomists. Each created simple relational tables, where the length of a long bone (e.g., the femur) was listed in relation to the average total stature associated with that measurement. While these relational tables were popular through the early twentieth century, they were soon surpassed by statistical approaches.

At the end of the nineteenth century, Karl Pearson, an anatomist, biometrician, and eugenicist, utilized the then-new statistical concept of linear regression to estimate statures from the femur and tibia (Raxter, Auerbach, and Ruff 2006). Pearson's method applied ordinary least squares (OLS) regression (see LINEAR MODELS and REGRESSION AND CORRELATION ANALYSIS), where individual long bones were used to predict living stature. The sample used in this study consisted of 100 French cadavers (50 of each sex), half of which were regarded as “senile,” although decreased stature due to advanced age was not considered by Pearson to be an important factor. Pearson devised formulae for each sex, but did not take proportional differences among human groups into consideration.

Yet, biological anthropologists increasingly noted differences in body proportions between human groups in papers published during the first third of the twentieth century. Aleš Hrdlička (a student of Manouvrier) noted proportional differences between the Lenape and Europeans in the tibio-femoral ratio (later named the crural index). William Ingalls, an anatomist at Western Reserve University, followed up on Hrdlička's findings, and determined that stature estimation equations cannot be developed and applied universally due to proportional variation among human groups; he did not develop new equations. Paul Stevenson, another anatomist, finally did in 1929, creating group-specific regression equations (for the Chinese) developed to address the mismatch problem (see Raxter et al. 2006).

Mildred Trotter and Goldine Gleser published the first widely used group-specific stature estimation OLS regression equations, first in 1952 using “white” and “black” females and males from the Terry Collection at the Smithsonian Institution. Later, they revisited these formulae for males following the Korean War, adding “Mexican” and “Mongoloid” samples. Eighteen years later, the authors published corrections for inconsistent measurements of the forearm bones in original studies. Later, Lee Meadows Jantz and colleagues demonstrated systematic mismeasurement of the tibia in Trotter and Gleser’s original studies. Thus, while these equations continue to be used, researchers have expressed caution about their application. Additional equations were soon calculated for the Japanese by Fuji, for South African groups by Allbrook, and for Mexican and Pueblo groups by Genoves. Various other groups have been added in subsequent decades. Collectively, these publications have created a body of literature promoting mathematical methods for stature estimation, all based on OLS regression of individual or a small number of skeletal elements against known statures.

At the same time as Trotter and Gleser (1952) were developing their equations, Georges Fully, a French anatomist and physician, was tasked with identifying Nazi death camp victims. Fully (1956) developed a technique for reconstructing stature by directly measuring skeletal element contributions to height and then using a correction factor to account for bone overlaps and missing soft tissue. This approach, the anatomical estimation method, relied on generally intact skeletal remains, and thus is impractical for frequent application within archeological and forensic contexts. Shortly after developing the method, and working with H. Pineau, he sought to address this by devising OLS regression equations for estimating missing vertebrae. Given proportionality differences among human groups, and a geographically limited sample, Fully and Pineau’s missing element estimation methods provided a limited solution to applying the anatomical method to incomplete remains.

Fully’s anatomical method was little used before it was revised by Raxter et al. (2006). Two exceptions are the publications of John Lundy (1985), who translated Fully’s original study, and Sculli, Schneider, and Mahaney (1990), who

used Lundy’s translated methods to develop the first mathematical stature estimation equations for human remains recovered in an archaeological context, and therefore did not present known statures. Sculli et al. (1990) reconstructed individual statures using the anatomical method, and then applied regression equations to estimate those statures from long bones. This was an approach later used by others to create regression formulae for estimating statures for groups recovered from archaeological contexts (e.g., Egyptians, North American groups, Andean groups, and preindustrial Europeans). The anatomical method continues to be tested and examined, including applying the method to fragmentary or incomplete human skeletal remains (e.g., Auerbach 2011).

Current methods

As reviewed, two approaches are most commonly used currently to estimate stature from skeletal remains: OLS regression from single or a few bones, and the anatomical approach from more intact remains. Based on citation frequency, regression-based methods are more regularly used, in part because of their utility in the case of incomplete remains. Accuracy and precision, however, are a concern in the use of regression methods. Regression allows for stature to be estimated from any osteometric dimension, but these do not provide consistent standard errors of the estimate (SEEs); long bones, such as the femur or the tibia, yield much smaller SEEs than metacarpals or metatarsals. Thus, it is important to document the estimation error for any estimate when using this approach.

The anatomical approach to stature estimation remains less commonly used, in part because it is not applicable to incomplete skeletal remains (Auerbach 2011). It has advantages over regression-based methods, as it takes stature reductions occurring with age into account, and is not subject to the mismatch problem between reference and analysis samples. While some minor differences in soft tissue thicknesses may occur among individuals, no study has documented a pattern to these differences among human groups (Ruff, Raxter and Auerbach,

2012). Thus, the anatomical approach is more universally applicable, but its requirements for skeletal completeness limit its application.

In addition to these two approaches, researchers have advocated for refinements to mathematical and statistical approaches to stature estimation. Researchers like Konigsberg et al. (1998) examined the statistical application of regression methods. Konigsberg and colleagues advocated replacement of OLS regression with Bayesian (see BAYESIAN STATISTICS) approaches, as well as maximum likelihood analysis to estimate statures. These methods are especially appropriate for estimating stature for isolated individuals from a known region or reference sample.

All of the studies documented refer to the estimation of stature in adults. Stature estimation among juveniles is a new area of study, with regression equations (based on radiographs of living individuals taken from the Denver Growth Sample) first developed by Ruff. Evaluation of these equations by Sciulli and Blatt showed them to have little difference from another sample of living individuals with known stature. Applications of these formulae to human remains from archaeological contexts are used with caution.

Applications of stature estimates

In archaeological contexts, stature estimations, regardless of method used, should be regarded as proxies for living statures, were it possible to have measured those directly. When stature estimates are applied to cases where individual identification is the goal, best practice calls for the estimation error to be reported, and the estimated stature to be combined with other sources of evidence, especially context. Provided mismatches are minimized and SEEs are small, averages for groups will generally be more accurate than individual estimates, as the latter are more statistically noisy due to variation within human groups.

Thus, stature estimations are most useful when making comparisons among groups, rather than when examining individuals. Mean stature varies among modern human groups, and the amount of sexual dimorphism in stature varies as well among groups. Mean adult statures among groups range

from 1.3 to 1.8 meters, although the upper mean continues to increase among post-industrial human groups on account of secular changes during the twentieth and twenty-first centuries. These changes are attributed to improved sanitation, better nutrition, decreased parasite loads, and reduced environmental stress. Therefore, one of the broadest applications of stature estimates to archaeological groups is the documentation of changes in these factors over time or between groups. Such comparisons may demonstrate caste or class differences between groups within a culture, or other sources of social inequality. These may also indicate changes in overall population health over time or across space.

An additional use of stature estimates is as a measurement of individual size. This is especially useful in studies of allometry, where stature is used as a standard against which the scaling of other dimensions may be determined (Auerbach and Sylvester 2011). Measures of height and size also serve an important role in developing models of lower limb kinematics in gait, and thus stature reconstructions are ideal in understanding mobility and, ultimately, the evolution of bipedal gait in humans.

Trauma

RYAN P. HARROD

University of Alaska Anchorage, USA

Trauma analysis in archaeological science is important because it provides insight into human behaviors (e.g., violent encounters or accidents that result in a reduction or loss of mobility) and also various cultural activities (e.g., mortuary rituals, ancestor veneration, trophy taking, and cannibalism). Connecting a traumatic injury on the body to a particular behavior or activity is challenging and involves understanding how the person was injured, why he or she was hurt, and the consequences of the trauma. Trauma analysis in archaeology requires a thorough understanding of taphonomy or what happens to a body after death due to natural and cultural processes (see TAPHONOMY), differential diagnosis, bone biology, and detailed reconstruction of the mortuary, site, and regional context.

Bones break in a variety of ways, and not all these are traumatic injuries. After an individual dies, natural physical and biotic factors cause taphonomic changes to the bone. Root etching, sediment abrasions, carnivore and rodent gnawing, trampling, and other forms of damage can mimic trauma on the skeleton. Researchers in paleontology, zooarchaeology, bioarchaeology, and forensic anthropology have conducted experimental studies to better understand and differentiate human-caused changes from taphonomic processes.

Differential diagnosis is the first step in the analysis because not all damage on bones or mummified tissue is the result of an injury. This process involves a systematic sorting out of all of the possible causes of bone changes, and then ruling out those diagnoses that do not exactly fit. Identifying traumatic injuries is a laborious process that uses an understanding of the full range of human biological diversity. Models and textbooks used to teach human anatomy and physiology often represent what

Susan Lawrence and Kae Bendixen (1992, 930) describe as “idealized” versions of the body. The problem with these representations is they do not depict the morphological variation that is present on different individual’s bones. The consequence of not teaching the full range of normal human variation in anatomy is the increased likelihood of misidentifying changes to a particular skeletal element as traumatic injury. The superficial temporal artery can cause a mark on the frontal bone, which researchers analyzing archaeological remains have misidentified as evidence of cut marks made by humans (Saul and Saul 2002, 82).

Knowledge of bone biology and biomechanics (how bones and related connective tissue respond to mechanical loads) is necessary for identifying both the type and timing of the injury. There are numerous types of injuries that can occur in the body. For example, Nancy Lovell (1997) identifies 14 fracture types for human skeletal remains. Specific fractures are a result of different forces being applied to the bone (e.g., spiral fractures, compression fractures), the age of the individual and the development of their skeletal system (e.g., greenstick fractures on children’s bones), and the location of the fracture, such as at joints (e.g., avulsion fractures). Having identified the type of fracture, it is important to determine when it occurred (e.g., antemortem (before death evidenced by healing), perimortem (at or around the time of death), and postmortem (after the person is dead) trauma). The three types of trauma are distinguished from one another because bone responds differently based on whether or not it can actively lay down new bone and the ratio of organic and inorganic material in each element. Postmortem trauma is typically considered a taphonomic process and not trauma because it happened well after the individual died. However, it is possible to cause trauma by desecrating human remains soon after death or, indeed, years after death. Most research on traumatic injury is focused on antemortem or healed injuries and perimortem trauma that happened at or around the time of death.

Interpreting the etiology or cause of a particular injury in an archaeological context is usually

the most difficult task associated with trauma analysis. Over the years, numerous studies have clarified how to identify whether a fracture was the cause of an accident such as a fall, an occupation-related injury, or a result of violence. Biomechanics, injury location, and fracture type have been highlighted as possible methods of identifying what caused the trauma found on bodies recovered from archaeological contexts, but just as important is the reconstruction of who this person was and what factors in their immediate cultural surroundings were like. The individual's lived experience can be reconstructed using other skeletal markers that include age at death, estimated sex, pathological conditions, dental and skeletal morphology, stature, and robusticity. Additionally, innovative methods for studying bones (e.g., X-ray and computed tomography (CT) scans, optical scanning, 3D modeling, isotopic analysis, and molecular anthropology), along with the reconstruction of mortuary context are crucial for identifying identity. Mortuary context reveals how the community might have viewed this individual after death. To get at this, analysis of the broader archaeological context and other sites in the region is necessary in order to better reconstruct the case history for the individual under investigation.

Often trauma analyses of skeletal remains have been very descriptive and focused on

single individuals as case studies, and while those are valuable, they are limited in aiding the full range of analytical possibilities that come with archaeological collections. The individual approach combined with the population assessment provides the necessary information for understanding the social and political factors that put people at risk for traumatic injury (e.g., captives and slaves, warriors, victims of abuse, refugees).

Zooarchaeology and Human Diet Reconstruction

CHARLES P. EGELAND

University of North Carolina at Greensboro, USA

In 1860, the paleontologist Édouard Lartet reported “incisions” on the fossilized bones of mammals, some of them locally or entirely extinct, that had been recovered in ancient deposits near Paris and elsewhere in western Europe. The morphology of these marks, he contended, could only have been produced by the slicing of human-made stone implements into fresh bone. Lartet’s findings, set as they were amid the mid-nineteenth-century debates on the antiquity of humankind, ultimately helped establish that humans had existed long before the Earth had taken on its present form. Though Lartet was not explicit about it at the time, the marks also implied that the flesh adhering to those bones had been butchered, and presumably eaten, by humans. Since then, the reconstruction of past diets has become a fundamental component of zooarchaeological analysis.

Here, diet includes those items among the spectrum of potentially edible animal resources that are consumed by humans. The selection of a diet is influenced by a complex web of physiological, sociocultural, and ecological factors that together comprise a subsistence strategy. To reconstruct the diets of past peoples with zooarchaeological data, analysts must: (1) identify the animal remains at a site; (2) be aware of preservation biases and excavation recovery techniques and their impact on sample adequacy; (3) sort out the remains that are linked to human dietary decisions; and (4) explore how these decisions fit into the wider subsistence strategy.

Dietary reconstructions rest on the correct identification of animal skeletal (vertebrates) or exoskeletal (crustaceans, molluscs, etc.) remains. While analyst skill and experience

play an important role in the identification process, factors such as fragmentation, state of preservation, the morphological distinctiveness or uniformity of particular taxonomic groups, the quality of the reference collection, and one’s research question(s) also determine the proportion of an assemblage that eventually is, or is not, identified (see ZOOARCHAEOLOGY).

Zooarchaeological assemblages represent a sample of the remains that were originally deposited. It is therefore imperative to evaluate if the sample under study reflects past dietary behavior with any degree of fidelity. Largely outside the analyst’s control are processes that can add to, subtract from, spatially reconfigure, or otherwise alter animal remains as they transform from a deposited assemblage into a preserved assemblage (see TAPHONOMY). Careful attention to context and the application of experimentally verified linkages between specific agents and their resultant traces can help identify the impact of these processes. Field recovery techniques must also be well thought-out. Decisions about screen size, excavation unit placement, and excavated volume should be made, within the constraints set by time, money, and research goals, to ensure that the recovered assemblage adequately samples the preserved assemblage.

Faunal assemblages, even those from archaeological sites, are the result of complex amalgamations of many events, only some of which involve human agency. Isolating those animals that were deposited by human dietary behavior is thus a critical, but by no means straightforward, task. The presence of animal remains in human coprolites is a direct and unambiguous sign of ingestion. Such evidence is extraordinarily rare, however, and may not necessarily reflect dietary consumption. Much more common are the modifications produced on bones and shells by butchery and consumption, which include the disarticulation of skeletons or exoskeletons, thermal damage, breakage, cut, chop, and saw marks, percussion marks, and tooth marks. While the presence of one or more of these can signal human involvement, nonhuman agents may

create very similar traces. Again, context and the use of experimental data can alleviate, though not completely eliminate, interpretive ambiguity. What is more, many of these traces are unintentional by-products, so not all of the butchered and consumed remains actually preserve evidence of those behaviors.

Once a faunal assemblage (or some portion thereof) is securely linked to human dietary decisions, the analyst can reconstruct past menus by simply listing the consumed taxa. Another approach is to determine the abundance of various taxa and, thus, their relative contribution to the diet. The most basic quantification units are the number of identified specimens (NISP) for each taxon and the weight of identified specimens by taxon. Zooarchaeologists also typically convert NISP or weight into derivative measures that attempt to approximate the amount of animals, skeletal parts, or potentially edible biomass represented by a faunal collection. While not without weaknesses, these measures are more easily translated into estimates of food value and, thus, often serve as units of analysis in studies of dietary choice and its role within a wider subsistence strategy.

The value assigned to an animal is contingent on an array of variables that include availability, cost, individual and/or group preference, nutritional yield, and social obligations. Anthropological studies among contemporary human groups commonly incorporate this information into quantitative and semiquantitative models to understand and predict the incorporation of animals into the diet. Fortunately, some of these variables can be accessed with zooarchaeological data. Availability and procurement costs, for example, are influenced heavily by seasonality—animals may only be available, or worth the effort to acquire, at certain times of the year. Age at death, which is reflected in the developmental stage of incrementally growing structures like teeth and shells, can help determine when over the course of a year an animal died and, thus, the timing of site utilization by humans. The nutritional value of an animal varies not only by age but also by sex, and the latter can be revealed through skeletal markers of

sexual dimorphism (e.g., antlers, body size). Some animals are imbued with special cultural meaning that often affects the way they are processed for consumption and distribution. Such treatment can result in specific patterns of modifications to their remains. When coupled with other datasets, then, zooarchaeology remains a key tool for archaeologists interested in reconstructing the diets of past peoples.

Zooarchaeology and Human Trade and Migration

JASON E. LAFFOON

Leiden University, Netherlands

The intentional control and movement of animals and animal resources can perhaps be considered a universal phenomenon as it is found among all societies. Since animals have been a major source of food and raw materials for most if not all human societies, we can infer that people have always been transporting animals and animal resources with them as they moved across the landscape, colonized new areas, and migrated between different regions. As such, although the archaeological record is equivocal, human-mediated animal movements have surely occurred since at least the Lower Paleolithic. Because nonhuman animals have the capacity to move independently and because many species can migrate long distances, it is often difficult to discern natural animal movements from human-mediated or anthropogenic transport of animals. For example, the wild ancestors of domestic dogs (*Canis familiaris*), the oldest domesticated animal in the world, may have contributed to their own domestication by following highly mobile groups of Paleolithic hunter-gatherers, and dogs have accompanied humans as they spread out to colonize many regions of the world.

Often the clearest zooarchaeological evidence for human migrations and trade is the presence of (exotic) animal remains outside of their natural ranges, a pattern that has been documented among a wide range of societies and time periods. For example, the presence of faunal remains of marine animals (shells, bones, teeth) in non-coastal archaeological deposits can often be most parsimoniously explained as resulting from human agency. These include the acquisition and transport of marine resources, not only for food

(fish, shellfish, and marine mammals) but also as raw materials for the production of various artifacts, which is evidenced by the presence of marine remains in inland geographic settings, sometimes dozens or even hundreds of kilometers from the nearest coast (Sayre, Miller, and Rosenfeld 2016).

The transport and trade of both living animals and animal remains is also well established for many terrestrial species, based on the identification of animals far beyond the limits of their natural ranges and sometimes across natural boundaries such as mountain ranges, deserts, or large water bodies. Zooarchaeological evidence indicates that the intentional and unintentional movements of animals were widespread and included such diverse categories as parasites, commensals, and tamed (pets), wild, and domesticated species. In fact, animals that have migrated with humans or are widely traded by them, especially domesticants, have become some of the most demographically successful and widespread species on the planet, and all domesticated animals have been to varying extents moved and traded by humans. Conversely, many wild animal species have suffered from extirpation (local extinctions) or extinction by human hands, either directly from hunting, fishing, and collecting or indirectly due to a variety of causes, including the anthropogenic introduction of predators, competing or invasive species, or other effects associated with human migrations.

Species translocations are the introductions of live animals into new territories by humans often, but not always, in the context of colonization and migration. The concept of transported landscapes (Anderson 1952), although originally focused on flora, is equally relevant for fauna and refers to the transport by humans of a selected subset of a region's biota from one location to another. Examples of transported landscapes have been widely documented globally and are perhaps most archaeologically visible in cases of trans-oceanic transport, where human intervention would have been required to move terrestrial species or their remains over vast distances of

DOI: 10.1002/9781119188230.saseas0625

open ocean (e.g., Laffoon et al. 2014). Perhaps the most well-known example of this process is the spread of pigs, dogs, chickens, and rats from maritime Southeast Asia to the major subregions of Oceania (Melanesia, Micronesia, Polynesia), where it is clear that no natural mechanisms could have accounted for such dispersal.

It can be difficult to distinguish between the movement of living animals and the movement of whole animal carcasses or the trade of animal parts or remains. In some cases, the presence of extant animal populations indicates that past movements included not only living individuals, but also reproductively viable individuals. In other cases, archaeological context, anatomical completeness, skeletal element representation, or evidence for modification and use can provide clues concerning the nature and function of traded faunal resources. For example, recent zooarchaeological and isotopic analysis of faunal assemblages from monumental contexts at Teotihuacan, Mexico (one of the largest ancient urban centers in the pre-Hispanic Americas) revealed the importation, captive management, sacrifice, and ritual deposition of wild carnivores, probably at the behest of local elites (Sugiyama, Somerville, and Schoeninger 2015). Similar cases of long-distance trade of animals and/or animal resources have been identified not only among other regional populations in Mesoamerica, but also worldwide. This highlights the active use and manipulation of animals in nonalimentary (social, political, ideological) domains of interaction.

The movement of living animals by humans also includes repetitive activities occurring within specific geographic ranges, such as herding, pastoralism, and seasonal mobility, which are integral to the subsistence economies of many diverse populations. These seasonal movements of animals can often be inferred via zooarchaeological datasets and related methods. Furthermore, animals and animal resources are some of the most common and widely circulated objects of exchange, and the development of large-scale networks has contributed to the movement of animal products several thousands of kilometers from their origins by ancient groups. The formalized trade of goods and products that characterizes market economies in many regions of the world has provided increased opportunities for the

flow of animals and animal products between people. In fact, one of the defining features of the Age of Discovery and of the subsequent Columbian Exchange (Crosby 1972) was the large-scale trans-continental movement of cultures, peoples, plants, and especially animals. The outcomes of these global interactions have had enormous and often irreversible impacts on the ecosphere, including the introduction of invasive species, widespread habitat alteration and destruction, local extirpations, mass extinctions, epidemics and demographic collapse, and permanently altered ecological systems. In fact, the ultimate effects of these historical processes on future environmental conditions are as yet unknown.

Traditional zooarchaeological methods and techniques including taxonomic identification and quantification have significantly contributed to our knowledge of past exploitation and use of animal resources (Reitz and Wing 1999), including the movements of fauna that occur via human migration and trade. In recent years, zooarchaeological research on these topics has been greatly enhanced by the development and application of various isotopic approaches, especially analyses of radiogenic strontium (see MOBILITY AND STRONTIUM ISOTOPES) and lead (see MOBILITY AND LEAD ISOTOPES) isotopes, as well as stable isotope analyses (see ZOOARCHAEOLOGY AND STABLE ISOTOPES) of carbon (see DIET AND CARBON ISOTOPES), nitrogen (see DIET AND NITROGEN ISOTOPES), sulfur (see DIET AND SULFUR ISOTOPES), and oxygen (see MOBILITY AND OXYGEN ISOTOPES) (Makarewicz 2016). A broad range of other biochemical (see HUMAN SKELETAL GEOCHEMISTRY) and biomolecular methods and techniques such as analyses of organic residues (see ORGANIC RESIDUE ANALYSIS) and aDNA (see ZOOARCHAEOLOGY AND ANCIENT DNA) are increasingly applied within the context of zooarchaeology (see ZOOARCHAEOLOGY) and bioarchaeology (see BIOARCHAEOLOGY). These advancements have greatly enhanced archaeological insights on human trade and migration and now permit a much larger corpus of evidence to be obtained not just from macroscopic faunal remains (bones, teeth, shells) but also from microscopic samples (proteins, lipids, aDNA). It is expected that current developments and future progress in a wide range of scientific disciplines

will continue to make substantial contributions to the increased accuracy of taxonomic identifications; expand the range of analyzable archaeological materials; and improve the identification of geographic origins and the determination of ancient routes of human migration and trade.

Chromatographic Techniques in Conservation

RICHARD NEWMAN

Museum of Fine Arts, Boston, USA

A recognized responsibility for conservators and scientists who work with cultural artifacts is examination, one component of which is the study of materials and manufacturing techniques. Both gas and liquid chromatography (GC and LC) are routinely applied to the characterization of certain classes of organic materials found in artifacts, and although not without limitations are the most versatile techniques for detailed analysis of many organic materials found in cultural artifacts. GC interfaced with mass spectrometers (GC-MS; see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) is now a fundamental tool in many museum scientific analysis laboratories. High-performance liquid chromatography (HPLC or LC; see HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC); also commonly interfaced with mass spectrometers, LC-MS) currently has more restricted applications, but will likely find more applications in the future. In addition to aiding in understanding materials used to make cultural artifacts, chromatography can play an important role in understanding deterioration or states of preservation of specific works of art, or the behavior of materials used in conservation or preservation initiatives. The preservation of cultural artifacts housed within a museum may be very dependent on the environment in which the housing takes place—display cases, storage cabinetry, air quality—and chromatographic techniques are also utilized to help evaluate this environment.

Thin layer chromatography, the earliest type of chromatography routinely used to study materials in cultural artifacts, has been largely supplanted by GC and LC. One of the earliest systematic applications of GC in the study of

works of art, published over 50 years ago, was the analysis of oils and fats in paint binding media. The compounds in fresh oils and fats (mostly triglycerides) are not easily analyzed by chromatography, but they can be broken down to yield smaller molecules (mainly certain saturated fatty acids, such as palmitic and stearic) that can potentially (along with other compounds formed during aging, such as azelaic acids) identify the nature of the original oil or fat, even when that original material has been severely altered. In works of art, oils and fats are most commonly encountered in paints; vegetable oils (those that are capable of “drying,” such as linseed, walnut, poppyseed, safflower, and tung) are the binder of oil paints. Egg yolk, another important historical paint binder in some parts of the world, contains a significant oil component.

Oils and fats are of considerable interest to archaeologists, and similar GC-MS analysis and sample preparation techniques are used for very old archaeological materials and comparatively much newer easel paintings created over the last few hundred years. Decades of GC-MS analysis of oil paintings in Europe has elucidated the history of the use of different oils; coupled with understanding of how different oils change upon aging, these have provided insights into choices made by individual artists. Medieval and early Renaissance Italian oil painters, for example, sometimes used two types of oil in single paintings—one (linseed) dried more quickly than the other (walnut), but the slower-drying one yellowed less during aging, a fact apparently understood by painters, who would use it with colors where yellowing would noticeably affect the color of a paint over time (whites turn yellow, blues darken or become greenish tinted).

Although egg yolk also contains some oil, its major components are proteins. Binders consisting entirely of proteins include egg white and animal glue (made up of the protein collagen). Proteins are complex molecules built from about 20 types of amino acids. Although many proteins contain the same amino acids, the relative amounts vary from one type to another. Hydrolyzing a protein into its constituent amino

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0091

acids, then separating and quantifying these by chromatography is a traditional method by which proteins have been and continue to be identified. Quantitative amino acid analysis by GC-MS (or, less frequently, LC) works well for distinguishing between some of the most common proteins in cultural artifacts. Egg has been identified as a paint binder, for example, in wall paintings from the 3000–2400 BCE Sos Furrighesos necropolis in Italy (Rampazzi et al. 2002) and the 1200 BCE Palace of Nestor in Pylos, Greece (Brecoulaki et al. 2012); and on figures from the “terracotta army” of emperor Qin Si Huangdi (259–210 BCE) (Bonaduce et al. 2008).

Glues, which contain collagen that can be easily extracted from connective tissues and other parts of many animals and from some fish, were common adhesives and binders in many parts of the world.

Among the limitations of amino acid analysis are the inability to easily distinguish between egg yolk and egg white, between different avian sources for eggs, and between different animal or marine sources of glues. Despite these limitations, amino acid analysis techniques by GC-MS will continue to be important in the future. Early identifications depended on the presence or absence, and relative abundance, of certain amino acids; statistical analysis has now become more common.

Another major class of binders that consists of very large molecules not directly amenable to analysis are plant gums, which consist of complex carbohydrates. These molecules can easily be hydrolyzed into simple sugars (monosaccharides), the small molecules from which they are formed. Analysis of monosaccharides (and uronic acids) liberated from plant gums has been a common method for identifying plant gums in cultural artifacts by GC-MS, and it remains the best of the currently available instrumental analysis methods for this purpose (Lliveras-Tenorio et al. 2012). There are less than a dozen common monosaccharides found in plant gums, and many of the same ones are present in different gums, so identification of a specific gum through monosaccharide analysis is not always straightforward. A study published over 40 years ago concluded, from GC analysis of monosaccharides, that fruit tree gums were utilized in some central Asian paintings dated back nearly two millennia. More

recent analyses have shown that plant gums were apparently common in ancient Egyptian tomb paintings, perhaps at least in some instances a type of *Acacia*, a genus from which the gum still used in artists’ commercial watercolor paints (*Acacia senegal*) is derived.

A class of natural materials very important in the archaeological and art fields is natural resins, exudates (insoluble in water) that come from many different types of trees. In the nineteenth and earlier part of the twentieth century, natural resins from many parts of the world were major constituents of commercial varnishes. Most natural resins exude from their source plants as very viscous liquids, often becoming hard, somewhat sticky solids after their natural solvents evaporate. They can be softened by heating, and in this semi-liquid form can be used as adhesives. Possibly the earliest use of natural resins may have been as adhesives to attach arrow points to wooden shafts. A type of *Pistacia* resin, from shrub-like plants that grow in northern Africa and elsewhere, has been identified as a varnish on ancient Egyptian sarcophagi. It evidently was melted and applied thickly and unevenly as a viscous liquid, often only to certain painted passages. Most natural resins undergo many chemical changes as they age, and the *Pistacia* on Egyptian objects is now dark and very yellow, undoubtedly much yellower than it had been when first applied. As an original component of a sarcophagus, conservators would not remove it even if it is somewhat disfiguring and considerably altering the appearance of the underlying paint. Another type of *Pistacia*, possibly not the same species as that used in ancient Egypt but chemically very similar, was a popular varnish for paintings in the nineteenth and twentieth centuries. Old natural resin varnishes, usually yellow, significantly affect the appearance of the underlying paint. As non-original components of paintings, these old varnishes are usually removed. GC-MS analysis is the analytical method of choice for identification of natural resins in all contexts. Specific resin identifications can be very important to a conservator’s decision regarding cleaning procedures. Some remnants of early original natural resin varnishes have been found in inconspicuous or hidden areas on Renaissance panel paintings, having survived cleaning procedures over the years. The study

of these, usually by GC-MS, sheds light on the nature of early picture varnishes.

Natural resins have been used for many purposes throughout the world and throughout history. In central America, resin used by the Aztecs as an adhesive, among other purposes, has been identified as a *Bursera* species (Lucero-Gómez et al. 2014). A very unusual natural phenolic resin, locally known as mopa mopa, was mixed with pigments by the Inka to decorate ceremonial qero cups (Newman, Kaplan, and Derrick 2015).

Natural resins were sometimes mixed with oils to modify the handling properties or appearance of the oil paint. Small traces of natural resins can be readily detected in small paint samples by GC-MS, and provide insights into the ways in which painters have manipulated their media for various purposes.

Limitations of traditional GC that impact or complicate its applications to cultural artifacts are that compounds must be analyzed in the gaseous state. In practical terms, this means that molecules must be relatively small and must be chemically stable at the temperatures commonly used with GC instruments (up to 300 °C). In the case of proteins and plant gums, large molecules not amenable to GC can be broken down into smaller compounds. These are still not directly amenable to GC, but can be reacted with various chemicals (derivatized) to forms (derivatives) that can be analyzed. (This is the case, for example, with amino acids and monosaccharides, and acidic compounds found in oils and resins.)

A pyrolysis (Py) attachment can be added to GC-MS instruments (Chiavari and Prati 2003). This permits small solid samples to be heated (in an oxygen-free environment), sometimes in the presence of a derivatizing reagent, to a very high temperature (typically 500–800 °C) that breaks down (pyrolyzes) large molecules into smaller fragments. The smaller fragments are then separated in the GC instrument. This procedure can be applied to virtually any complex molecule, protein and complex carbohydrates included, and is a relatively straightforward means of analyzing many samples. Another advantage is that vastly different classes of materials can be simultaneously detected, although often not specifically identified. Traditional GC sample preparation

requirements often work on one class of materials, but other samples would be needed for other classes of materials, ultimately requiring multiple samples and considerable labor.

Amber, the general name for fossilized resins, is virtually insoluble in all common solvents, and consists, for the most part, of polymeric material. Yet Py has proven to be an excellent method by which different types of ambers can be identified.

One unusual natural material, which utilized the sap from several types of trees that grow in a number of Asian countries, is lacquer. The sap, whose chemical composition has only been elucidated recently in any detail, forms a solid, impervious film when exposed in fairly thin layers to air at a certain relative humidity. Due to clear compositional differences, the major types of lacquer plants can be easily distinguished by Py GC-MS. In recent years, a systematic study of export lacquer objects, made in Asian countries for the European market, has utilized Py GC-MS to characterize (at least in part) the astonishing number of components that could be present in a single lacquer sample, which could include more than one type of natural lacquer, oil, natural resins, and proteins (Schilling et al. 2016).

Towards the end of the nineteenth century, the fledgling chemical industry began to develop many synthetic materials, including modified natural materials (cellulose nitrate, for example) and entirely human-made substances, such as synthetic dyes and pigments. Plastics were embraced almost as soon as they were invented by some artists, and characterization of these synthetic materials, which often exhibit significant conservation problems, is important. Py GC-MS has proven to be one of the most useful techniques to identify plastics. Synthetic paint media were first used by some artists in the 1930s and 1940s, and in the 1960s acrylic emulsion artists' paints came into use. Acrylic emulsion paintings present unusual cleaning problems to conservators, and research on such emulsions in the conservation field often involves GC-MS and Py GC-MS as major analytical tools. The plastic substrates of modern sculptures also have been studied.

Another type of sampling procedure, most often used in conjunction with GC-MS, is solid-phase microextraction (SPME), which was

invented in 1989. It “collects” certain organic compounds onto a solid fiber (the compounds can be in a water solution, or in air). The solid fiber is placed in the GC inlet and the trapped compounds desorbed by heating, then separated in the GC. In the conservation field, the technique is being actively explored as a means of identifying and possibly quantifying certain compounds that are released by materials used in constructing storage or display cases for cultural artifacts. Cases are often fairly (or very) airtight, and volatile compounds given off by materials of construction may become concentrated in the case. Some of these (for example, formic and acetic acids and formaldehyde) are known to be potentially hazardous to some materials that have been used to make artifacts. SPME provides one means of identifying a range of volatile compounds given off by case construction materials (fabrics, plastics, wood products, etc.)

HPLC and LC-MS techniques have far fewer routine applications in museum science laboratories at this point in time than GC-MS techniques. Over 30 years ago, LC was first applied to identification of natural dyestuffs in textiles, and it is currently the technique that can provide the most detailed compositional information on natural (and many synthetic) dyes. Natural dyestuffs in particular often contain numerous compounds, making chromatography a logical approach to their full characterization. As in the case of GC-MS, many laboratories throughout the world utilize generally similar chromatographic procedures, meaning that LC or LC-MS data from one institution can often be directly related to those from another institution. As one example, there are several natural dyes that are extracted from insects (cochineal of several types, kermes, and lac are the main ones) and these can be readily distinguished individually or in mixtures by LC. Some textile dying involves simultaneous use of dyes of several kinds, and LC can often unequivocally identify all of them during a single analysis.

LC was recently used to identify the presence of indigo in 6,000-year-old cotton fabrics from Huaca Prieta on the northern coast of Peru (Splitstoser et al. 2016), in a region in which cotton was first domesticated, perhaps a century or more before the time when the indigo-dyed fragments were made. The same major compounds are

found in indigo dyes from many types of plants that grow in various parts of the world, but the Peruvian source may have been an *Indigofera* species. From this same relatively arid region of South America are the stunning early dyed textiles from the Paracas culture. Among the very well-preserved dyes are reds derived from a type of madder plant. Many plants given this general name are known and have been used throughout the world. The native South American types probably belong to the *Relbunium* genus.

Ion chromatography (IC), a form of HPLC, has been used to identify anions associated with deterioration of monuments, in runoff water or in corrosion products. Quantitation of formic and acetic acids in the air inside storage or display cases can be carried out by IC analysis of the acids captured with specially prepared diffusion tubes. Size exclusion or gel permeation chromatography (SEC or GPC), other forms of HPLC, have been used to determine molecular weight distributions of materials in conservation and preservation studies.

Conservation

ROBYN SLOGGETT

The University of Melbourne, Australia

What is conservation?

Conservation is defined as “all measures and actions aimed at safeguarding tangible cultural heritage while ensuring its accessibility to present and future generations.” This definition was adopted by the International Council of Museums–Committee for Conservation (ICOM-CC), in 2008. It reflects the fundamental document that describes what conservators do, *The Conservator-Restorer: a Definition of the Profession* (ICOM-CC 1984) that “set forth the basic purposes, principles, and requirements of the conservation profession.” It also reflects the principles that have guided the activities and aims of professional conservation practice since UNESCO auspiced the establishment of the International Centre for the Study of the Preservation and Restoration of Cultural Property (ICROM) in Rome in 1959.

The activities of conservation include technical examination, preventive conservation, remedial conservation, and restoration framed by the philosophy that all conservation action must respect the physical properties of the object and its significance. These basic tenets of conservation are defined within professional codes of ethics and codes of conduct around the world (see ETHICS IN CONSERVATION).

The *Definition of the Profession* provides the framework for the ways in which conservators work together, and also with other professions and disciplines, in order to “comprehend the material aspect of objects of historic and artistic significance in order to prevent their decay and to enhance our understanding of them so as to further the distinction between what is original and what is spurious.” Being able to discern what constitutes an authentic cultural record is an essential part of conservation and archaeological

professional practice, and is the basis of all academic enquiry and good scholarship.

Conservation and archaeology

Conservation and archaeology are, essentially, interdisciplinary activities, and the tenets of conservation, thorough examination, minimization of risk, preventing deterioration and damage, and respect for cultural and historical significance, are the responsibility of all professions involved in ensuring access to and study of heritage (Matero 2008). Conservation provides the frameworks, evidence, and knowledge to ensure that decision making involving the preservation of the cultural record is properly informed and rigorously assessed.

Archaeologists and conservators share an obligation to properly document and preserve the cultural and scientific records with which they engage. Both disciplines seek to interrogate materials, investigate their condition, and understand their production, in order to uncover, present, and preserve information about the past. Sharing knowledge and providing cross-disciplinary education and advice is important from the time archaeological material is first uncovered, until it is finally located in a study collection or exhibition. While many archaeological excavations may not have a conservator on site, the conservation profession retains its responsibility to provide education, advice, and develop standards that reflect this shared responsibility.

The conservation process

Examination

A comprehensive technical examination is the first step undertaken to understand the object, to best manage its condition, and inform decision making. Examination is “the preliminary procedure taken to determine the documentary significance of an artefact” (ICOM-CC 1984). During examination the original structure and materials of the object are assessed, and the findings, along with any determination of the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0112

extent of any deterioration (DETERIORATION), alteration, and loss are documented. This process is critical in ensuring verifiable evidence-based decision making.

After the initial examination is complete a research or treatment pathway can be determined, and where necessary the analytical pathway can be proposed. As a general principle examination and analysis proceed from basic visual analysis to the utilization of lab-based techniques and then to high-end analytical techniques. This means there is not one defined analytical pathway relevant to every investigation, and only in specific cases is complex analysis required.

Documentation

Documentation in conservation is “the recording in a permanent format of information derived from conservation activities” (AIC 2016) (see CONSERVATION DOCUMENTATION). Good documentation supports all levels of decision making in conservation and is essential in providing information about the object, its condition, and any past intervention or modification. Established procedures for conservation documentation include the preparation of a condition report that identifies the object, its context, and its condition, and includes recommendations for its future care. In the case of a collection or site a collection survey will provide the same information. Documentation will usually include photographs of the object and may also include a technical examination report comprising scientific analytical findings (see OPTICAL MICROSCOPY; RAMAN SPECTROSCOPY IN CONSERVATION; and OPTICAL SPECTROSCOPIES) as well as a treatment report that documents any conservation intervention undertaken on the object and data associated with technical analysis, such as spot testing or infrared spectra (see MICROCHEMICAL TESTS IN CONSERVATION and RAMAN SPECTROSCOPY AND MATERIAL ANALYSIS). It is important that conservation documentation adheres to industry standards so that object identification and research dissemination are unambiguous. Glossaries that assist with the description of materials, methods, deterioration, and conservation activity are provided by ICOM-CC, IIC and national bodies such as the American Institute for Conservation (AIC) in the United States, and

the Institute for Conservation (ICON) in the United Kingdom, and others. Object ID (ICOM n.d.) is used globally as an agreed format for object documentation, and the ICOM/CIDOC Documentation Standards Group, 2017 Definition of the CIDOC Conceptual Reference Model (ICOM/CIDOC Documentation Standards Group 2017) is another useful tool for the documentation of heritage.

Conservation research

Rigorous research enables good evidence-based conservation practice, which is critical when conservators are making decisions about treatment, risk management, or providing advice to other professionals such as archaeologists. By its very nature archaeological material will have been subjected to chemical, biological, environmental, or physical factors that will have impacted on the condition of the material as well as, potentially, on the ability of researchers to study this material. Different classes of materials respond in different ways to their environment. A piece of glass lying in a salt-rich damp environment, for example, will behave very differently to one in a dry tomb environment (see CONSERVATION OF VITREOUS MATERIALS). The method of manufacture will also affect the reaction of the object to the environment, both physically and chemically. Objects achieve equilibrium with their environment and the changes involved when objects are removed to a stable museum-standard environment may severely damage the object. Conservation research, therefore, brings together an understanding of the construction and materials comprising the object, with an understanding of the effect of different environmental conditions, and of deterioration processes, and combines this with knowledge of possible preservation or treatment options, in order to properly inform decision making about excavation, transport, storage, treatment, and display. Conservators work closely with scientists in various fields to employ relevant techniques (see ELECTRON MICROSCOPY IN CONSERVATION; GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS); and INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) and conservation scientists provide special

expertise within the profession (CONSERVATION SCIENCE).

Preventive conservation

Following examination and the completion of relevant documentation a decision can be made whether to preserve the object without treatment, or to undertake remedial conservation or a more interventive restoration. This is an important distinction. Preservation seeks to minimize any need to intervene in the physical structure of an object. ICOM-CC's *Definition of the Profession* describes preservation as "action taken to retard or prevent deterioration of or damage to cultural properties by control of their environment and/or treatment of their structure in order to maintain them as nearly as possible in an unchanging state" (ICOM-CC 1984). Preservation programs are supported by a range of policies and procedures that address environmental conditions, ensure safe handling and maintenance procedures, deliver integrated pest management and manage risk, including emergency preparedness and response, and in cases of digital records, the migration, reformatting or duplication of these records (AIC 2008). An example of preservation on an archaeological site could include the use of anoxic enclosures, relative humidity buffers to provide stable environment suitable for a salt-laden potsherd or keeping waterlogged material at the correct saturation to prevent damage (see CONSERVATION OF WATERLOGGED MATERIALS). Conservation triage is a short-term preventive measure that ensures the object is secured while longer term preventive or treatment options can be assessed.

Conservation planning

Conservation plans are produced as part of a preventive conservation program, but may include recommendations for conservation treatment (see CONSERVATION PLANS). In archaeology, conservation plans may involve a site management plan for material left in situ, a packing and transport plan to move items from the site to a storage facility, and a long-term conservation management plan for material held within an institution or in long-term storage. A conservation plan may also include recommendations for prioritization

of treatment or interventive conservation, and will provide advice on various possible actions.

Treatment

Conservation treatment involves direct intervention aimed at retarding or preventing deterioration. There are a number of levels of intervention within conservation treatment including remedial conservation and restoration.

Remedial conservation

If the object is unstable or damaged then a decision may be made to undertake remedial conservation, described as "all actions directly applied to an item or a group of items aimed at arresting current damaging processes or reinforcing their structure" (ICOM-CC 2008). Remedial conservation is interventive but primarily aimed at stabilization.

Restoration

Restoration, on the other hand, is primarily concerned with intervention to an object that is generally stable but which can no longer be properly visually or structurally understood. Restoration is specifically aimed to facilitate a better understanding and appreciation of the object, and support its continued use. While most restoration modifies the appearance of an item, restoration undertaken by a conservator is based on respect for the original material and manufacture, and is only undertaken when the significance of the object has been compromised by previous alteration, damage, or deterioration. An example of restoration could include infilling loss in a pot and inpainting the fill to make it less conspicuous so that the original esthetic of the piece can be appreciated.

Conservation specialization

Conservators generally work within a particular specialization such as paintings, paper, objects, or textiles, or as conservation scientists focusing in particular on scientific examination and assessment. ICOM-CC has 21 working groups that reflect special interests in areas that

include object types such as Graphic Documents, Objects from Indigenous and World Cultures, and Paintings; areas of practice such as Preventive Conservation, subjects such as Documentation, Education and Training in Conservation, and Scientific Research; and others. One group, Wet Organic Archaeological Materials (WOAM) is concerned with the degradation and conservation of organic archaeological objects found in wet or damp sites, researching and advising on in-situ conservation, reburial, and site surveys, as well as postconservation treatments of objects of organic archaeological materials (see ENVIRONMENTAL MANAGEMENT WITH FIRE).

Finally, conservators are also concerned with the conservation history of an object. The need to understand the location and effect of previous interventions is an important one. For example, adhesives degrade and often numerous layers of different adhesives exist on one object (see POLYMERS IN CONSERVATION). Some remain reversible and do not affect the object; others cross-link with age, becoming increasingly irreversible; and others become tacky attracting dust, or become embrittled, causing lifting and sheeting of surface and edges. Understanding the effect of previous interventions, including their deterioration pathways, and the possible options for removing them in the future, is essential prior to any conservation work.

Conservation Documentation

YOSI POZEILOV

LACMA Conservation Center, USA

Heritage conservation activities are varied and expansive, hence the documentation performed in each of these activities can vary a great deal. Conservation work is performed on heritage materials found in museums, cultural institutions, archives, and in situ. It spans the gamut from paper-thin to architectural and monumental, made from inorganic, organic, and composite materials, as well as virtual or electronic. For the purpose of this publication we will concentrate our attention on the physical world and on objects made from organic and inorganic materials.

Conservation activities can be categorized in different ways such as: condition reporting, preventative, intervention or remedial treatment, and academic (scholarly and research). According to the type of conservation activity being performed, different types of documentation can be generated. Documentation is defined as creating a physical or virtual record of the history, condition, examination, and research of an artifact that can be created in various forms such as: image-based, text-based, and data-based (analytical results). The different conservation activities can generate any or all of the documentation types just mentioned. The documentation types are not mutually exclusive and in most cases are used in combination, normally giving more weight to one type of documentation while the others have a supporting role. For example, if a conservator is to create a condition report of an art object, then the main type of documentation generated is most likely to be image-based condition reporting in which annotating and mapping of an image would be the main method used to describe the object's physical condition. Additionally, a text narrative could be used to explain condition, not readably visible on the image, and when further explanation is needed

to describe a more complex condition. Another example would be the surveying of an archaeological site using aerial photography; images obtained during this process are then used to generate photogrammetric models that provide accurate measurements and information on the site.

Documentation performed during condition reporting should reflect the state of the heritage material at the time of its inspection. Using image-based condition reporting means that images are annotated and conditions are mapped either by hand in a physical print(s), or digitally with the use of tablets or handheld computers, to represent different attributes present in the object. This documentation can be done most efficiently through a well-established imaging protocol, that involves a consistent approach to a number of steps from image capture, color processing, and naming, to storage, just to mention a few. This report also contains the tombstone information related to the object and when necessary a descriptive narrative of a condition not observed in the marked images. Condition reporting is heavily used during the loaning and borrowing of a heritage object. The lending and receiving institutions use this documentation to track and monitor any physical changes that may take place on an object during its transportation and handling through time and the participating venues.

When a heritage object undergoes examination and treatment, documentation is done at different stages of the process. This includes images of the object before, during, and after conservation treatment, recording the state of the object at each phase of the intervention, including a record or description of techniques or procedures involved, materials used and their composition, and the nature and extent of all alterations. In many cases before the treatment commences a thorough examination of the object is necessary. This may include technical examination through the use of microscopes or high magnification equipment, X-ray imaging, as well as noninvasive and nondestructive scientific analysis like X-ray fluorescence (XRF)

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0113

and fiber optic reflectance spectroscopy (FORS). During this initial examination documentation can and should be generated in the form of images, spectra, graphs, datasets and text, whenever possible. This initial documentation should provide support and guidance during the course that the conservation treatment takes place. This information should be compiled in the treatment proposal document explaining the planned treatment and procedures, alternative approaches, and the potential risks.

Documentation of heritage materials needs to contain all pertinent information pertaining to the cultural property in question, as complete and accurate as possible. These records should include all the images, diagrams, maps, GPS location, text narratives, condition reports, sampling areas, scientific analysis, as well as description of structure, materials, and relevant treatment history. All documentation should clearly describe and identify (accession number, series, owner, etc.) the heritage property, the individual(s) involved in the treatment and examination, at all stages of the conservation work, and the dates in which examination takes place. This information can be attached to the physical object's dossier or in a digital archive storing digital documents, images, and datasets, when possible if these electronic files support metadata fields they should be populated with the pertinent information.

Documentation needs space to be stored and archived. In many instances we only think about the generation or production of the documents that make the documentation body, but it is as crucial to think about the storage and long-term archiving of this body of knowledge since it becomes an important part of the stewardship of the heritage property. Using the previous examples, the image-based condition reporting will generate marked images and text documents that can easily be saved as printed physical documents or as open source digital documents that are easily accessible by any computer system like a .pdf document and a .jpg image, requiring relatively small physical and digital storage space. In contrast, the photogrammetric approach taken for the land survey generates datasets that are very large in volume. Typically, a series of images are combined to generate files that are very large in size. These are impractical to print, and in their digital format are very heavy in data due

to the tridimensional models that they generate. As a result, their digital storage space needs are very large, and furthermore accessing and working with these files requires specialized software and greater computing power to be used efficiently.

Documentation should follow guidelines established under a well-defined framework; these guidelines can be specific to an institution or organization so as to achieve consistency and uniformity in the information generated, as well as in the way that it is stored. Guidelines have been established by professional institutions like the American Institute for Conservation of Historic and Artistic Works (AIC). In the *AIC Code of Ethics* we find that documentation is expressly stated under section VII: "The conservation professional shall document examination, scientific investigation, and treatment by creating permanent records and reports" and it is more specifically delineated in the *Guidelines for Practice* under the section titled "Documentation" where it states that "The conservation professional has an obligation to produce and maintain accurate, complete, and permanent records of examination, sampling, scientific investigation, and treatment..."

What this abiding principle does not state is the form and content of the documentation. It is then incumbent on individuals, organizations, and institutions to establish the best way to represent their heritage, and comply with this code of ethics.

In conclusion, we can say that conservation documentation is used for: establishing the condition of cultural property; providing information important for the understanding and past and future treatment of the object; helping with the appreciation and understanding of an object's aesthetic, conceptual, and physical characteristics; and providing knowledge and a permanent record that can avoid misunderstanding and litigation.

Conservation in Museums

PAMELA HATCHFIELD

Museum of Fine Arts, Boston, USA

Introduction

The discipline of conservation in museums today must be understood within a number of different contexts. First, consideration must be given to: first, how the discipline itself evolved; second, the nature of the cultural heritage housed in particular types of collecting institutions, including how, where, and when it was acquired; and third, the purpose envisioned for the institution and its constituencies. These aspirations and activities are surmounted by the overarching responsibility of all collecting institutions to preserve and protect the materials of heritage for future generations.

The scope of conservation in museums reflects the missions of those institutions, focusing on collecting, accessibility, and preservation. Particularly in the West, archaeological collections formed through excavation center on care, preservation, and education, rather than collecting. For university collections, particular emphasis is given to pedagogical activities, research, and training, requiring more handling and use of materials than is typical in other kinds of collections. As illicit activities commonly associated with early collecting practices are increasingly scrutinized and corrected, emphasis has shifted to preservation and accessibility. Without material evidence gained through scientific excavation, the research value of such objects is greatly diminished, as is the research value of their sites of origin. Nevertheless, looting of antiquities and their acquisition by some collecting entities persist. Conservators and conservation scientists work with curators to explore material aspects of objects such as old restorations, burial encrustations, and residues, to help establish

provenance, aiding in the clarification of the history of objects. This evidence plays a critical role in determining whether objects should be acquired or retained in museum collections today.

Forming collections

The history of collecting traces back to the valuing of the rare and beautiful—for adornment, ritual practice, and preservation in ancient burial practices. Certainly the spoils of war were collected and revered over time; houses of worship preserved treasured objects and relics, and privately owned cabinets of curiosities proliferated by the seventeenth century. By the eighteenth century, the study of the antique became a serious profession, coinciding with astonishing finds from Herculaneum, Pompeii, Egypt, and other sites in the classical world, necessitating more formal museums, and a more formalized approach to care and preservation. In 1683, the donation of a private collection formed the nucleus of the Ashmolean Museum at Oxford, regarded as the first modern museum.

Archaeological collections in museums were amassed by participation in excavations and expeditions, and also by gift or purchase. The earliest excavations, lacking in rigorous documentation or any awareness of the importance of preservation, lost valuable information. Today, archaeological methodologies, and the preservation of context, are essential in our understanding of societies through objects preserved in collecting institutions. However, an inherent tension exists for these collections; when incorporated into an art museum, objects may be presented in an idealized rather than purely informational or educational light. These choices impact treatment decisions, the preservation of research potential, how objects are visually presented, and how artifacts are sampled, handled, and utilized.

History of care and restoration of collections

The earliest origins of the discipline are found in several arenas, include the skills of craftsmen fabricating tools, structures, and objects of daily use, and fine artists creating adornments and objects of devotion. The instinct to preserve, repair, and refurbish items of value, and ritual practices performed in the burial of loved ones and dignitaries forms the basis of the modern discipline of conservation. As early as the first century BCE in *De Architectura*, Vitruvius commented on the importance of environmental damage to archival materials and objects. W. Newton's translation of this text into English became available during the late eighteenth century, and may have resonated with observers of the effects of burial, storage, display, or industrial environments on the appearance and condition of artifacts. Along with Homer's description of smoke damage to Odysseus's armor in Book 19 of the *Odyssey*, these can be considered the earliest acknowledgment of the importance of preventive conservation.

Although reuse and repair of ancient monumental or sculptural stone and other materials is documented throughout history, it is clear that as early as the thirteenth century, renowned artists like Arnolfo di Cambio had already employed the practice. Renaissance artists considered it a right of passage to "restore" ancient works of art, and many artists of the day, including Donatello, Verrocchio, Michelangelo, and Cellini, practiced the art of restoration in diverse media. Repair evolves into increasingly sophisticated and sometimes intentionally deceptive practices whose intention was to mislead the viewer about condition, age, materials, or other characteristics.

Once museum collections were established, observation of the deterioration of objects from excavations factored into the development of the modern discipline, closely allied with the development of chemistry, physics, and other sciences. A robust tradition of restoration developed alongside the introduction of chemistry applied to the preservation of museum collections. Museums sponsoring excavations in the late nineteenth to twentieth centuries managed the handling,

preparation, packing, and shipping of sensitive objects in the field, compounded by the rigors of handling, travel, and fluctuating environmental conditions. No one was more critical to this development than Friedrich Rathgen, who, in 1888, became the first Chemist-in-Charge at the Chemical Laboratory of the Royal Museums of Berlin. Extensive deterioration of bronzes and stone prompted the director to consult chemist Otto Olshausen, who formed the first true conservation laboratory. Shortly after, he published *Di Konservierung von Alterumsfunden* (*The Conservation of Antiquities*), which, translated into English in 1905, became the cornerstone of the developing field of conservation in the English-speaking world.

The collector or curator, observing alterations in objects, especially deterioration, endeavored to understand and correct such problems. In Baltimore, Henry Walters amassed one of the most significant collections of ancient bronzes in the United States, establishing the Walters Art Gallery in 1904. Shortly after his death in 1931, a scientific laboratory was established there, to understand and mitigate the damage observed by "corroding canker," today known as "bronze disease," or active chloride corrosion. In 1895, this condition had been thought a contagious disease requiring sterilization, treated at the Museum of Fine Arts, Boston (MFA) with the help of Dr. Harold C. Ernst of Harvard Medical School (Figure 1).

Development of technical study

By 1813, Humphrey Davy, inventor of electrochemistry, investigated the composition of pigments from an ancient color shop in Pompeii, drawing comparisons between those and other colors found in ancient buildings in Rome. By the mid-nineteenth century, the National Gallery of London was concerned enough about the effects of pollution on paintings that eminent scientist Michael Faraday was consulted.

After finding antiquities stored underground during World War I drastically altered, a scientific laboratory was instituted at the British Museum in 1918, to aid in understanding the

Figure 1 William J. Young, founder of the Department of Restoration, later the Research Laboratory, at the MFA, formed in 1929.

deterioration and to develop methods of repair, restoration, and preservation. The idea that museums were the proper depository for the world's treasures stemmed from a colonial bias that only the elite could properly care for these precious objects, whose history was not merely that of their country of origin, but all of western civilization.

In Europe, chemists formed scientific departments to address problems of deterioration evident soon after objects were excavated, such as damage from soluble salts and the “canker” of copper alloys. Around the turn of the twentieth century, Rathgen published treatment methodologies for vast quantities of salt-laden Babylonian clay cuneiform tablets in perilous condition.

Objects arrived in museum collections already treated in the field. Such treatments were conducted with limited resources and time. Although many objects would not have survived untreated, subsequent conservation focuses on challenges caused by those treatments, rather than original condition problems. These materials are equally important when considering further treatment, storage, display environments, and future analytical work. The limited excavation history of many objects compromises our understanding of the chemical constituents around the object, and

their possible origins—original, burial, treatment, storage, or display.

In an art museum, the ways in which an object is interpreted, treated, displayed, or stored may be determined on aesthetic or historical grounds, rather than in consideration of inherent research potential. Treatment may involve complete restoration or aesthetic reintegration, allowing the object to be seen as intact. Such decisions are based on the curator's understanding of the material at a given moment in time, and may change as new information comes to light or analytical techniques provide previously inaccessible information. University collections consider the pedagogical and research potential of objects, illustrating concepts in the history of art and archaeology and inspiring students through the experience of learning from artifacts made by ancient craftsmen.

Examination and technical study

Modern museum conservation laboratories perform: examination, documentation, treatment, and preventive conservation. Objects are examined when considered for acquisition by gift or purchase, for exhibition or loan, when questions arise about condition, alteration, state of preservation, past treatment, or restoration, or arising through new information or technologies. Provenance issues concern many museums. The MFA's Curator of Provenance researches the provenance of objects in the collection, as well as those considered for acquisition. Conservators provide material evidence used in support of the conclusions reached about the provenance of each work.

Examination begins with visual inspection under magnification, identifying original materials, burial deposits, damages, interventions or alterations, physical weakness, or chemical instability. Reflectance or luminescence of the object viewed under different wavelengths of light (such as ultraviolet or infrared) reveals important information about original materials and past treatments, including the nature of pigments, resins, or adhesives not visible under normal lighting conditions.

Radiographic methods visualize cracks, joins, and internal structures, revealing the nature and extent of interventions and restoration. Dense materials such as stone and metals require high energy to penetrate, requiring additional imaging methods, for example, gamma radiation. Ground-penetrating radar has proved useful in detecting cracks and pins in objects. Other techniques such as neutron transmission imaging may detect organic materials within metal objects, and letters written on papyri scrolls from Herculaneum have been visualized through X-ray phase-contrast tomography.

Radiographic methods give critical information on structure and restoration, but previous exposure may alter other test results such as thermoluminescence dating. Other analyses are compromised by past history, storage or exhibition conditions, or previous treatment, whether objects have resided in collections for years or are recently acquired.

Techniques such as multispectral imaging reveal traces of color, underdrawing, residues, recarving, restoration, and other details not

apparent under normal lighting conditions. For example, traces of Egyptian blue are revealed when imaged using visible induced infrared luminescence (VIL) (Figure 2).

Organic pigments, binders, coatings, and adhesives may reflect ultraviolet radiation or may be stimulated to emit light when viewed under ultraviolet wavelengths of light (ultraviolet reflectance (UVR), or ultraviolet induced luminescence (UVL)), revealing traces of color or binders not visible to the human eye under normal lighting.

Computational photographic techniques such as reflectance transformation imaging (RTI) enhance surface details using a computer program to synthesize information gathered from multiple photographs of an object taken with the camera and subject in the same position while altering the angle of the light source at regular intervals. Such methods register and collate tiny variations in the reflectance of surface texture or topography, revealing original methods of manufacture, inscriptions, and other details not visible under normal conditions.

Figure 2 Sandstone head of Tutankhamen where broad stripes of Egyptian blue appear bright white when photographed using this technique. MFA11.1533.

Such techniques reveal new information about how objects were decorated. For example, Classical sculptures, once assumed to be unadorned, are today understood to have been highly colored with ornate decorative schemes.

Some museums and university collection conservators work alongside conservation scientists, who apply analytical techniques to answer questions about material components, burial accretions, and residues, and characterize evidence of past treatment or repair. These identifications help provide an understanding of the original materials, their history, and their current condition, in addition to providing clues to burial context.

Documentation

The process of examination is documented visually, through photography, and detailed in writing, as are treatment procedures and recommendations for display, storage, and future care. Proposals are produced in writing for the curator and discussed, and agreement is reached prior to any treatment of artifacts. These procedures are outlined in professional codes of conduct such as the Code of Ethics and Guidelines for Practice of the American Institute for Conservation of Historic and Artistic Works (AIC 2018).

Preventive conservation

Preventive conservation occupies significant resources and attention in the museum laboratory. Conservators understand the nature of materials in museum collections and how they respond to agents of deterioration such as light, extremes of temperature, relative humidity, and pollutants. They identify conditions that may result in instability or damage—such as soluble salts from burial, or active corrosion—and work to provide storage or exhibition conditions that will slow deterioration. Conservators and scientists study construction, padding, mounting, and packing materials which may interact with artifact materials, producing harmful changes

in the condition and chemical structure of objects.

Conservators work with exhibit designers, preparators, and collection care specialists to ensure that stable materials will be in proximity to objects installed in exhibit cases. Fabrics, support or mount surfaces, inks used on labels, support films for graphics, even the coverings used on lighting cables are all tested to identify potential sources of acid, sulfur, or other substances that interact with object materials. Packing methods and materials are similarly examined.

Conservation treatment

Objects undergo conservation treatment for a number of reasons. First, and most importantly, objects are treated in order to correct physically or chemically unstable conditions, including active corrosion of metals, flaking polychromy, waterlogged wood, powdering stone or ceramics, or damage from soluble salts in stone or ceramics (Figure 3).

Objects are also treated to reveal details or inscriptions important in understanding the object, including reduction of corrosion products or burial encrustations, while preserving information within these residues. They may also be treated for aesthetic reasons, to restore an appearance, aligning with current knowledge. Such restoration is carried out using stable, reversible materials which are easily removed should future interpretation change. By contrast, irreversible techniques like electrolytic reduction of corrosion products are today only sparingly used.

Staffing

Conservation laboratories are staffed with professional conservators with varied expertise. In Europe and elsewhere, often training focuses on the development of expertise in particular materials, for example: stone; glass, and ceramics; wooden artifacts; and wall paintings. In the United States, training generally focuses on the following disciplines: objects and sculpture; paintings; furniture and frames; textiles; prints,

Figure 3 Consolidation (strengthening) of powdering Nubian sandstone with methyl-trimethoxy-silane, a compound that bonds directly with silicon in the stone, forming a three-dimensional network. Source: Photography © Museum of Fine Arts, Boston.

drawings, and photographs. Conservators may have expertise dictated by the nature of the collections and, in some museums (for example, the Kelsey Museum at the University of Michigan), concentrate only on archaeological and ethnographic collections. In such cases, conservators are integrated into active and ongoing archaeology education and field excavations.

Conservation training

Today, most conservators hold graduate degrees from recognized training programs, and many are professional members of the AIC or other professional conservation organizations worldwide. Their training encompasses art history and archaeology, chemistry and physics, materials science, studio art techniques, ethics, risk assessment, and conservation methods, including treatment and preventive techniques. Candidates

for graduate training programs in conservation spend several years in pre-program internships or training positions before embarking on the application process. Some training programs focus on this area of conservation. An understanding of the interests and needs of the archaeologist in the field and the curator in the museum collection is critical to the handling, examination, analysis, storage, and restoration of artifacts. Field experience helps greatly to align the priorities of conservators, archaeologists, and future generations of stakeholders.

University of Bradford, UK

Animal remains are among the most prolific of archaeological finds and provide evidence of environmental conditions and diverse human activities (see ZOOARCHAEOLOGY). Animal soft tissue, including skin, muscles, and the internal organs, normally only survives in conditions where biodeterioration has been prevented by environmental factors (freezing or desiccation) or by the presence of preserving chemicals (tanned leather, embalming or bog bodies). In most archaeological contexts it is only the hard tissues, such as bone and teeth, that survive to be recovered (see TAPHONOMY). These hard tissues are biocomposites of a structural protein stiffened with a mineral, generally a form of calcium hydroxyapatite called bioapatite. They fall into two groups: osseous tissues, such as bone, antler, and teeth, formed from the protein collagen and highly mineralized; and keratinous tissues, such as horn, hoof, baleen (whalebone), and tortoise-shell, formed from the protein keratin and having a very much smaller mineral content. All these materials were used widely in the production of cultural objects after various degrees of work on them (see BONES AND IVORY). Whole small teeth, for instance, were used as amulets or sewn onto garments through the simple addition of a single perforation. The large tusks of animals such as mammoth, elephant, hippopotamus, walrus, and sperm whale were usually more heavily worked on, to remove the outer rind (cementum) and any traces of enamel, so as to reveal the easily carved dentine of the tooth, known as ivory. In order to understand conservation procedures for osseous and keratinous materials, it is essential to understand the degraded states in which they may be encountered.

Horn and other keratinous tissues rarely survive, because proteins are liable to chemical breakdown in alkaline (high pH) burial conditions and are also highly susceptible to biodeterioration by microorganisms in almost any situation where moisture is available (O'Connor, Solazzo, and Collins 2014; see DETERIORATION). Their recovery is unusual even in waterlogged sites—except in peat bogs, which provide anoxic, acidic (low pH) conditions and contain plant-derived biocidal compounds that inhibit biodeterioration. When the protein in bone or ivory is lost, there is nothing to hold the mineral component together and, even if bone is recovered from an excavation, when it dries out it can crumble into small fragments. The mineral component of these hard tissues is susceptible to dissolution in acid conditions. This loss of mineral is least serious for the survival of keratinous tissues, where it is present in very small amounts, but can be devastating for osseous tissues. As the mineral is stripped out, tissue loses its stiffness and collapses. The bone and antler recovered from the highly acid contexts at the Mesolithic site of Star Carr in Yorkshire, England were black, flattened, and flexible and had a fibrous texture resembling decayed leather (High et al. 2015).

As both acid and alkaline conditions can destroy osseous tissue, it may seem surprising that so much of it survives burial. This is due to the intimate way in which the protein and the mineral are combined. The collagen matrix protects the bioapatite from acid attack, while the bioapatite protects the most vulnerable parts of the collagen from alkaline attack and from biodeterioration by microorganisms (Collins et al. 2002). The result is that bone, antler, and ivory are surprisingly stable, except in extremes of pH. Even so, while these materials may remain recognizable and relatively robust, staining, cracking, an increase in porosity, surface erosion, and the addition of chemical contaminants may all occur, affecting the conservation requirements and information potential of the material. Water movement is critical. The rate of deterioration

of bone, for instance, is greatest in free-draining deposits in areas of high rainfall, as the water percolating through the bone will have a naturally low mineral content and a high oxygen content, promoting dissolution and biodeterioration respectively (see *DETERIORATION*). The best preserved bone—meaning bone with little alteration in porosity, largely intact collagen matrix, and minimal dissolution or replacement of bioapatite—can therefore be found in sediments that are anoxic and have little or no water movement, such as consistently waterlogged fine silts. Extremes of preservation can sometimes be seen within a single bone where the burial environment changes, as in the mammoth long bones from Lynford in Norfolk, England, which were submerged partly in silts and partly in layers of river gravel (O'Connor and Larkin 2012).

Arid sites present a different challenge. Groundwater movement is predominantly from depth to the surface, so buried bone experiences periodic wetting by water that is rich in dissolved minerals, in alternation with periods of drying during which those minerals can precipitate or crystallize within the bone structure. This causes dimensional stresses that manifest themselves as extensive fracturing, made worse by the loss of resilience as the collagen matrix is rapidly lost.

The deterioration of these biomaterials is also determined by their structure. Osseous tissues can be vascular, having an integrated blood supply, or nonvascular. Bone and antler are vascular tissues, and it is the organization of the blood vessels and the bone matrix around them that largely determine the patterns of deterioration. Long bones have a longitudinal grain and are often distinctly layered, so loss of collagen can lead to longitudinal splits and exfoliation of the surface layers. Antler is a disposable form of fast-growing bone that is laid down and shed annually. Like long bone, it has a longitudinal grain but the structure of the compact tissue is more chaotic in antler, so it does not form conspicuous layers and the cracks that appear are rarely straight. The degree of the mineralization that has occurred is also important, hence immature bone and antler, which are not so highly mineralized, are often less well preserved than mature bone from the same context.

The blood supply to teeth is entirely within the soft pulp tissue at the core of the tooth. The dentine is built up over the surface of the pulp in successive fine layers. Microscopic dentinal tubules pass through these layers, facilitating the movement of fluids throughout the tooth during life. Postmortem deterioration of dentine is predominantly expressed as radial and concentric cracking. When observed through a hand lens, these cracking patterns and the fine lamellar, nonvascular structure enable the worked ivory to be distinguished from bone. Dentine is also more highly mineralized than bone, and teeth with a protective cap of enamel can persist in graves long after the skeletal bone has completely deteriorated. However, ivory is much more susceptible than bone to significant dimensional changes if the water content of the collagen varies; so, as freshly excavated ivory dries in the air, shrinkage can open cracks and cause warping.

The precise details of the cracking, together with features in the dentine such as banding or patterns produced by the organization of the dentinal tubules, allow ivory of different species to be identified (Penniman 1952; O'Connor 1987). Elephant ivory, for instance, is formed from nested, oval cones of dentine and is very susceptible to splitting between these layers, producing characteristically shaped concentric cracking in transverse tusk sections.

The keratinous tissues are resinous-looking, tough, more or less flexible thermo-softening materials. In their raw state, horns, hoofs, baleen sheets, and turtle carapace scales (tortoiseshell) are distinctly different in shape, color, reflectance, translucency, and patterning; but both work and decay can greatly alter these attributes, making identification particularly problematic. Where they do survive wet burial, they are generally very fragile, matt, opaque, and dark brown or black, unless they are stained by metal corrosion. Fortunately these materials are all structurally different, and the visibility of their structures can be enhanced by decay (O'Connor, Solazzo, and Collins 2014). Cattle horn, for instance, develops over a bony horn core from skin keratinized layer by layer. As the horn tissue is dead, there are no blood vessels or nerves in this material; but, examined under low magnification, the cross-section is clearly made of finely

corrugated layers. On the surface, these corrugations appear as regular longitudinal ridges that are very distinctive of cattle horn. As the horn deteriorates further, these layers take on the appearance of longitudinally aligned fibres and finally disintegrate.

Many other factors can affect the state of preservation of hard tissues, for instance cooking or other processing designed to convert the raw material into an artifact. Material exposed on the surface before incorporation into sediments will be in poorer condition than material directly buried in rubbish pits or graves and, in the case of keratinous material, may not survive at all. Damage through trampling, abrasion, or gnawing of osseous material may be seen along with signs of weathering such as erosion, cracking, or flaking, which may be concentrated on particular surfaces where the material lay exposed and undisturbed (see TAPHONOMY). Bone grave goods may appear to be very much better preserved than the skeleton in the grave. The immediate environment of the skeleton will have been modified by the mass of rotting soft tissue and the vascularization of the skeletal bone will have provided a pathway for the spread of gut microbes during putrefaction. These organisms attack the bone from the inside, increasing its porosity and the potential for chemical dissolution over time. It is often observed that bone in the core of the body and closest to the gut is in poorest condition.

The most common form in which evidence of keratinous tissues survives is as mineral preserved organic (MPO) remains, where they have become infused with metal corrosion products (Janaway and Scott 1989). MPOs may go unrecognized on site, only becoming apparent during conservation. Solutions from corroding metal such as iron seep out into the surrounding sediments, where they react to form a solid crust around the original object. Organic materials directly adjacent to the surface of the metal can become incorporated in this crust, which forms a persistent mold or cast of the material's macrostructure and traps chemical traces of the organic material. How extensive and detailed these remains are is a function of the rate of decay of the organic material and of the speed with which the metal corrodes. Preservation can be further enhanced if the corrosion solutions are biocidal, as this will

inhibit biodeterioration. Traces of horn handles are frequently found on iron knives and swords, but in this decayed fibrous state many are mistaken for wood (O'Connor, Solazzo, and Collins 2014). Better preserved horn is mostly found in conjunction with bronze, brass, and debased gold and silver objects, as the corroding copper in these alloys forms a very effective biocidal solution.

The core aim of conservation is the preservation of information, and this can be challenging when we are dealing with animal hard tissues, because they can embody such a wide range of information (see ZOOARCHAEOLOGY). The most crucial time for these materials is the period during which they are uncovered. Uncontrolled drying in direct sunlight or exposure to repeated freezing and thawing or wetting and drying can lead to surface-detail loss, fragmentation, or complete destruction. If spreads of bone debris or assemblages of artifacts cannot immediately be lifted from site, a covering can be used to protect them from direct sunlight and frost damage or to maintain moisture levels and thus prevent soluble salts damage by minimizing the recrystallization of minerals within the bone.

The recovery of bone and ivory is discussed by O'Connor and Larkin (2012). Most osseous finds are relatively small and robust, and can be lifted from site by hand or by inserting a ridged board beneath them, to support them more evenly. If objects need extra support, as do skulls filled with sediment, crushed objects, or objects that can no longer support their own weight, they are often lifted in a plaster jacket that provides close-fitting external support. Direct strengthening of the objects themselves by resin consolidation before lifting is less desirable. Although it can help retain the object's structural integrity and surface detail, resin impregnation can also compromise its potential for radiocarbon dating or biomolecular analysis. Sediment inevitably becomes stuck to the surface of the bone, and removing this sediment and adjusting the position of misaligned fragments will require additional conservation work at a later stage. If the use of consolidants cannot be avoided, the material may need to be sampled prior to consolidation. Forward planning and liaising between all the specialists is crucial and conservation advice must be sought in order to determine the most appropriate

consolidant, whether a solution or an emulsion should be used, the optimum concentration of the resin, and the method of application that is best in the given circumstances (Johnson 1994). For instance, in wet conditions a resin solution will not penetrate the material but will form a skin on the surface of objects, while emulsions may not set while the object remains wet. In both cases the object will not be consolidated and may collapse when it is lifted or during transportation. Inorganic minerals have been proposed as alternative consolidating agents but remain experimental (North, Balonis, and Kakoulli 2016).

Sediments are cleaned from excavated bone and ivory using water and soft brushes in good lighting conditions. Toothbrushes are too harsh and even when used on well-preserved bone can result in polishing of the surface. The material should not be soaked: the surface is wetted, holding it above the water by hand so that the conservator can be confident that the brushing is only removing sediment and not abrading the surface. Rewetting dry material can cause the collagen to swell and fracture so water usage is kept to a minimum. Bone which is quite soft upon excavation may well become harder and more robust as it slowly dries in the shade or laid out within a well-ventilated building. It may take some days for bone to dry to the state that it can be packed away. If the bone is colder to the touch than the ambient temperature it is probably because water is still evaporating from it and it should be left to dry for longer. Ivory is given special attention because it can crack and warp during drying and may continue to break up when stored in environments with varying temperature and relative humidity. Very slow drying and stable storage conditions are important, but if ivory shows any signs of damage as drying progresses the material will need to be consolidated. Reconstruction, gap-filling, and mounting of these materials are demonstrated by Larkin (2010).

Where keratinous materials survive it is essential to maintain as closely as possible the conditions that have preserved them, for example, waterlogged or desiccated, until they can be actively conserved. Wet materials are stored in closed containers in dark, refrigerated conditions to reduce the risk of accelerated biodeterioration while they await conservation.

Biocides such as dichlorophen or disodium ortho-phenylphenate are best avoided because of their toxicity and because they can cause chemical deterioration of the degraded material. Wet storage is only a temporary measure and growth of fungi and other organisms can be prevented by refrigerated, dark storage. Ultimately the material needs to be both stable and dry. "Dry" does not mean "desiccated": the material should be dry enough not to lose further water at the ambient relative humidity of the store, and not desiccated below that ambient humidity. Air drying can cause shrinkage and patterns of break-up that reflect the structure of the material. For example, horn may warp and exfoliate as free water is lost, becoming hard and brittle. Once dry it can slowly continue to lose water held within the decayed protein, opening cracks and increasing fragility. Consolidation combined with controlled drying or freeze-drying techniques have been used to overcome many of these problems (Kaye, Cole-Hamilton, and Morphet 2013).

Bone will always contain a proportion of moisture but this will vary with the relative humidity in the air around it so it is liable to "sweat" if it is sealed in plastic containers and temperatures in the storage area fall. Such condensation can promote mould growth so bone should be held in open-topped or perforated bags within acid-free card boxes that allow a slow exchange of air with the storage environment. A thin polythene foam sheet cut to the size of the bag and inserted behind an object can provide a standard level of physical protection for worked osseous objects but fragile objects may need to be housed in padded boxes. Longer-term passive conservation of conserved bone, ivory and horn is essentially all about good short-term treatment and packing followed by long-term stability of curation conditions.

Conservation of Earthen Building Materials

MARIANA CORREIA

Escola Superior Gallaceia, Portugal

LUIS GUERRERO

Universidad Autónoma Metropolitana-Xochimilco,
Mexico

Introduction

Earth (clay-rich soil) has been used as a building material since antiquity and throughout the history of humankind, though only recently has earthen architecture become scientifically accepted as a discipline of its own. Earthen architecture has been present in the five continents and reveals a wide range of cultural diversity of expressions, forms, techniques, and building styles through its historical heritage. Currently, there are still 15–17 percent of people living in earthen settlements (Correia 2016).

In recent decades, more interest, focus, and research have been given to the conservation of earthen heritage. World Heritage plays an important role in increasing worldwide interest, especially considering the outstanding value of some of the earthen sites that are at great risk. Creation of the *UNESCO World Heritage Earthen Architecture Program (WHEAP)* was meant to disseminate the international significance of this exceptional and fragile heritage. The survival of this heritage is a challenge that needs to be addressed with thoughtfulness, knowledge, and humbleness.

There are several publications on earthen architecture conservation. Most address the conservation of individual sites, and very few publications compare the different intervention approaches (Warren 1999; Matero and Cancino 2000; Mileto and Vegas 2014; Gandreau and Sadozai 2014; Correia, Guerrero, and Crosby

2015; Correia 2016). Consequently, this fact limits, in a way, the opportunity to establish critical reflections on the level of success and to apply the obtained results in present and future actions (Guerrero, Correia, and Guillaud 2012).

Unfortunately, there are great difficulties conserving earthen structures and preventing their decay. Several reasons for this can be identified: inadequate and inefficient intervention, lack of follow-up and maintenance, lack of preparation of the team members, incorrect intervention interpretation, and lack of material knowledge.

Failure of the physical condition of the structures may result from lack of action or discontinuation of conservation measures and conservation practice. However, as earth is such a fragile material, inaction to protect and conserve, in some instances, can endanger the timely preservation of the last remains. As defended by Cesar Brandi, sometimes the site can be beyond recovery, if the unity principle addressing the archaeological remains as a whole is not present anymore (Correia and Fernandes 2006).

Recurrent failure can also occur due to the use of incompatible materials and methods applied by professionals without enough specific knowledge or experience in earthen heritage conservation. More accurate testing and assessment is required before the use of new treatments and stabilization materials.

Universal solutions are also sometimes employed, using only one intervention approach. The problem might lie in the lack of research and knowledge of the material compatibility, its reversibility, and long-term impact. A clear understanding of earthen architecture, different earthen building styles, integration of local knowledge and skill, identification of seismic performance, differences of behavior regarding new intervention, a critical view of different intervention approaches, and their impact on the earthen fabric are required to encourage a change towards the conservation of this fragile heritage (Correia 2016).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0117

This is why a comprehensive knowledge of the different technical strategies of conservation should be documented and further critically assessed, before an informed decision can be made, as each case is unique. Different technical strategies can be considered, such as preventive measures, modification of the earth mixture, use of consolidants, and structural reinforcement.

Preventive measures

One measure that in general guarantees safe conservation of earthen heritage is *reburial of the excavated structures*. Although this is an extremely drastic strategy with strong implications for the site value and accessibility, it provides priority to its comprehensive preservation in the long term. However, the procedures to rebury remains that have already been excavated, exposed, and documented should be extremely cautious, as once the site is reburied, it would be difficult to monitor the original remains. That is why, for the protection of very damaged earthen archaeological structures, the use of membranes

such as geotextiles is recommended, which have the quality of physical barriers that allow the natural flow of water through the soil and the archaeological remains.

A less radical measure is the designing and placement of *protective shelters*. This measure has been proven effective for several decades in some cases, and ineffective in others due to wind dynamics. It has the advantage of favoring public visit to the sites, while protecting the site from possible damage caused by rain, wind, snow, or hail. However, any change in the temperature and humidity of the earthen structures sets their material integrity at risk, as much of their stability is derived from the equilibrium they possess with the amount of water they contain. An excessively humid earthen structure can disintegrate, but the same happens if the earthen structure is too dry, as it loses cohesion. As a result, when choosing shelters to cover earthen sites, the main aim should be the hygrothermal balance of the interior spaces. Shelters can also dramatically alter the visual relation of the archaeological sites. Therefore, their form, height, and materials must be carefully and sensibly designed (Figure 1).

The structures exposed to the elements, and those protected by shelters, will require a preventive conservation intervention, involving a direct physical intervention, as, for example, the application of a *surface coating*. For a more balanced approach, it is indispensable to consider the hygrothermal requirements needed for earthen structures. This will protect the earthen structures from possible surface damage, without impeaching the natural permeability of the building components. Among the most frequently used technical strategies is the use of capping on the top of the walls (e.g., thatch), especially on walls that have lost their integrity. Also common is the use of sacrificial coatings on the top of the walls, and earthen renders on the vertical exposed surfaces.

For an adequate wall adhesion, these coatings are often made with an earth mixture like the original fabric, with the possibility of subsequent removal, as the reversibility principle should be considered. Sacrificial coatings generally have a higher amount of gravel or other aggregates, which improves erosion control and site stabilization. The surface coating should not be more rigid and impermeable than the original earthen fabric that needs to be protected, and it should

receive regular maintenance. In earthen heritage, conservation should be part of a continuous preventive activity.

The use of geotextile membranes to protect the earthen structure before applying the surface coating can also be considered. These are often used on the reburial of excavated structures, as previously mentioned. They are useful because once covered with sacrificial coatings, they allow the natural flow of water vapor in the structures, generate a surface protection barrier, and can be removed when required. However, the membrane selection and application and its earthen coating should be addressed carefully. It often happens that, upon application, the elements and components of the site that were covered are no longer recognized, and the architectural value of the component is lost (Figure 2).

Modification of the earth material

Modified earthen materials usually create a more durable fabric. This can be achieved through stabilizers, additives, and adhesives that can turn the natural soil into a more effective earth

mixture. These materials can be organic or inorganic, of natural or synthetic origin. *Stabilizers* are materials that modify the physical and chemical characteristics of natural earth, increasing its resistance to mechanical stress, as well as to the effects of moisture (Correia et al. 2015). The most common stabilizer is lime, but fired gypsum has also been used for a long time to improve the earth mixture. The earthen material that forms the sacrificial coatings, as well as some components designed to fill gaps in the original building systems, are often stabilized. This process consists of the modification of the natural qualities of the earth to allow it to acquire a greater mechanical resistance, adhesion, water resistance, and porosity.

For decades, cement was used as a soil stabilizer, or as a surface coating when addressing earthen heritage intervention. It was believed that its use could avoid periodic maintenance and could provide a more effective response to harmful weathering agents. However, as it has been widely documented, cement is incompatible with earth, due to its relative difference in permeability, mechanical strength, and contraction–dilation coefficient. This difference generates dynamisms within the earthen structures that progressively degrade it. The impermeability of cement traps water vapor inside the earthen material, which ultimately leads to the destruction of the structure. Therefore, its use is not recommended, and extensive interventions have been planned to carefully remove the cement capping.

Additive is a general term for substances that do not interfere with the chemical reactions of clay, but which provide a physical activity that improves its properties. Sand is one of the additives most frequently applied to balance the expansive and detractive activity of argillaceous soils (Correia et al. 2015). Different additives can be used, such as pulverized fly ash (PFA) and natural additives such as egg white, cactus juice, straw, chaff, wood chippings, and animal hair.

Several different additives have survived as part of the intangible vernacular knowledge. This is the case, for instance, with mucilage, juices, and gums of vegetable origin, as well as some animal proteins, which offer greater consistency to the earth mixture and improve its adhesion. This also improves the water resistance of the material,

while maintaining the permeability of water vapor through the material. This is important because the earthen wall constantly balances air and humidity between the interior and exterior. A similar effect is achieved by adding small proportions of lime or gypsum to the earth mixture. These agents produce chemical reactions that with time provide a greater mechanical and water resistance to the earth mixture.

Adhesives are emulsions that bond soil particles together and are primarily valuable in attaching plasters to their substrates. The most common emulsions are acrylic emulsions, such as “copolymers of ethyl acrylate, methyl methacrylate, and/or ethyl methacrylate” (Oliver 2008). Some authors do not recommend the use of emulsions, due to their difficult penetration when there is an absorbent material, but also because they have no reliable additives in terms of material aging.

Use of consolidants

A consolidant is a material that is applied on surfaces to establish cohesion of the particles, thus providing greater protection against surface weathering. On earthen walls, *inorganic consolidants*—aqueous solutions and/or dispersions of different salts—are commonly employed. Once applied on surfaces, through the soil capillaries, they stabilize the clays and agglutinate them to smaller-size particles. This group includes substances used in traditional maintenance, such as limewater, potassium aluminum sulfate (alum), and alkaline silicates (sodium or potassium) (Correia 2016). They can be applied through spray or by paper and brush absorption.

There are also traditional materials, such as *natural organic consolidants*. This is the case with animal glue, gum, beeswax, egg white, casein, natural cactus juice, and so on. Each one has a different impact on the earthen surface. Some have a lower penetration than others, or can react with sensitivity to humidity. Others are more prone to biological attacks and can change color with time. Natural cactus juice is commonly used in Latin America, as it has a good balance between availability, price, and short-term impact, despite some experts arguing that for medium- and long-term impact it does not present enough positive outcomes.

Concerning the *synthetic organic consolidants*, several products have presented good results, as is the case with silica ester, ethyl silicate, polyvinyl alcohol (PVA), and polyvinyl acetate. One of the most popular products is ethyl silicate, due to its good penetration and longer lasting results maintaining the color and the wall's earthen fabric in good state. In Huaca de la Luca, Trujillo, Peru, it has been successfully used for over 20 years. However, its high cost restricts its use and sustainable application.

Silicone and synthetic resins are also frequently applied for surface protection. However, authors restrain their use for surface exterior treatment, as they tend to form a film on the surface and "with the exfoliation of this film and the detachment of the treated part, more damage is done to the surface to be protected than if it had not been treated at all" (Alva and Chiari 1995, 105).

Structural reinforcement

For the repair of damaged structures, *nonintrusive structural reinforcements* provide an option. When the damage to archaeological remains is so severe that their unity, load-bearing capacity, or survival are at risk, it becomes necessary to integrate systems of structural support. These systems must be carefully designed, so as not to alter the natural performance of earthen structures. Physical and chemical compatibility is essential in this case to achieve continuity in the transfer of mechanical stresses by filling-in missing parts. This is possible by applying mud grouts to fill-in cracks, or using bonding mortars to replace disintegrated earthen material. In the case of lacunas, the size of the gap should be considered to balance the structural filling. This does not mean that the original material must be replicated, as this could lead to the ethical dilemma of reconstruction and historical falsification. Unfortunately, this is a frequent choice in the case of earthen heritage, which is incorrectly chosen, as it is often considered by professionals that earthen reconstruction is acceptable in archaeological heritage, when it is not in other materials.

There are conditions in which the severity of the earthen archaeological remains guides the intervention design for radical adjustment

regarding its transfer of loads, which only becomes possible through *intrusive structural reinforcement*. Because of earthquakes, differential sinks, flooding, or similar agents, the relation between the structural components can be interrupted, so that it becomes necessary to incorporate components that bind them together again. The introduction of supports allows the components to separately acquire a new condition of structural stability as isolated units. In both cases, it is necessary to consider that the difference between the strength of the remains and the reinforcements must be the smallest possible to avoid these measures being more harmful than beneficial.

Structural reinforcements made of wood, bamboo, or vegetable fibers have been found to be compatible with earthen structures, since they have similar coefficients of strength and dilatation. However, it is important to take care of the transition points between these reinforcements and the remains, so that balanced stress distributions are developed, instead of load concentrations.

In case there is a need to use materials with greater resistance than wooden structures, stone, brick, and even steel components have been used. However, it is necessary to generate a gradual unloading process in transition areas, allowing a gradual passage from a highly resistant material to the earthen built material. Intrusive structural reinforcement should be the last option for intervention and not the first choice to consider, as the principle of minimum intervention is essential when addressing earthen heritage intervention.

Conclusions

The development of intervention procedures for the conservation of earthen built heritage should be flexible, enabling suitable solutions for each case. It is necessary to consider the individuality of each site and that the conditions of the different sites need to lead to specific solutions. This is why documentation and registration of the different results obtained during conservation actions are required, in order to have a critical assessment of their level of success or failure, according to the specific conditions in which they were developed.

When addressing the conservation of earthen structures, one of the most serious errors is the search for a “permanent” solution. The development of expensive works addressing incompatible materials, cement-based mortars, or structures of reinforced concrete has led to irreparable damage to earthen heritage.

History of earthen architecture reveals that its structures are closely related to the societies that have inhabited them and have continuously maintained them. Thus, the solution for the preservation of this heritage should be based on a proper design of management processes from different time frames, based on consistent procedures. These actions necessitate the participation of communities to which the heritage belongs; thus, within planning for the management of the sites, actions to recover traditional knowledge and the practical transfer of earthen technology are of great importance (Guerrero 2015). The integration of local intangible heritage is part of a site’s living traditions and preservation.

Lack of planning and strategies definition can involve reactive, instead of proactive, actions, which in the case of earthen architecture could have irreparable loss. A greater number of experts and conservation professionals with certified education on earthen heritage conservation would increase the quality standards and the expertise in the field.

For a balanced conservation approach addressing earthen archaeology, a comprehensive course of intervention needs to be established for each site, involving different stakeholders, an interdisciplinary expert team, and consideration of the different indicators of quality and of best practices.

Conservation of Fibrous Materials

ELIZABETH BURR

Arizona State Museum, USA

The class of organic fibrous artifacts includes a range of raw plant materials and construction technologies, including categories such as basketry, textiles, and paper. Though common among many past societies worldwide, the presence of fibrous artifacts in the archaeological record is rare due to their perishable nature. Preservation conditions limit organisms causing biodeterioration and offer protection from fluctuating environments that cause chemical and mechanical breakdown, such as repeated wetting–drying cycles. Most often, fibrous artifacts are recovered from anaerobic waterlogged sites, or from spaces that offer added protection within an arid environment, such as in a cave or sealed vessel. Typically, they are found in fragmentary and weakened degraded states, particularly when recovered from waterlogged sites. Their preservation may be due to chemical transformation, such as charring or mineralization, in which the form of each individual fiber is retained. Additionally, fibrous artifacts are often found in association with human remains, which can impact artifact preservation, and this adds additional ethical considerations to their study and conservation. The conservation of fibrous artifacts includes first-aid recovery in the field, examination, preventive conservation measures such as creating storage mounts, and treatments to clean and stabilize artifacts.

“First-aid” recovery

Significant damage can occur to fibrous artifacts during excavation and added caution is often needed. Fibrous artifacts may require “first-aid”

in the field during recovery to prevent rapid deterioration and damage. Block lifting is beneficial in either arid or waterlogged ground, wherein the surrounding earth is excavated and encapsulated along with the artifact (Jones et al. 2007). Subsequently, the artifact can be transported and carefully excavated by an expert such as a conservator working in a controlled environment. Artifacts recovered from a submersed environment should be kept damp and either chilled or frozen until controlled drying can be performed. Artifacts may require temporary consolidation or support during excavation without impacting future potential for carbon-14 dating, which can be accomplished using cyclododecane (Pohl et al. 2009). Care should be taken to minimize alterations to the artifact during excavation; folds and distortions should be left, and permanent measures such as consolidation with an adhesive are not advised.

Conservation study and examination

Initial conservation examination includes identifying materials and construction technology, as well as an assessment of condition and photo documentation. In-depth study of archaeological fibrous materials is often conducted by conservators because of their skillset and training, which can be useful to archaeologists in providing additional information on recovered artifacts. Fiber identification is important for understanding the artifact's context and degradation, and for determining optimum treatment. Natural raw materials derived from plants are cellulosic fibers, all of which have diagnostic features that make their identification possible, often to a genus or species level. When taxa are indeterminate, it is still beneficial to identify key features that categorize fibers, such as distinguishing between bast, leaf, and seed fibers of plants. Fiber identification is most often achieved using microscopy and comparative examples of known fiber types. Diagnostic technological information is also recorded, such as the fabrication structure (i.e.,

DOI: 10.1002/9781119188230.saseas0118

the weave or looping structure of a textile), fiber processing technology (i.e., the twist and ply of yarn, or the splitting of basketry elements), design patterns, and surface decorations. If the surface is obscured by dirt or accretions, it may be necessary to first clean the artifact before a technological examination can take place.

Additional analysis using nondestructive or microdestructive means may be conducted to further identify materials such as residues and dyes, and to examine the extent of deterioration and effectiveness of conservation treatments. Analytical methods presently used in the research of fibrous artifacts include Fourier transform infrared spectroscopy, gas chromatography mass spectrometry, surface-enhanced Raman spectroscopy, X-ray fluorescence spectroscopy, and scanning electron microscopy (Brettell et al. 2017; Maccerrelli et al. 2016; Fischer 2009).

Preventative conservation

Because of their fragile and often fragmentary state, it is crucial to minimize handling and provide full support to fibrous artifacts while both stored and studied. Though the solutions may be simple, the impact of preventing further damage can be substantial. All permanent support mounts should be constructed with archival materials, provide ridged though often padded support, and allow the artifact to be visible without requiring handling to view. Supports may be as simple as a padded archival grade tray or box, though more fragile or awkwardly shaped items may require additional support and immobilization. A number of case studies demonstrate optimal strategies for designing appropriate storage for fibrous artifacts (Margariti and Loukopoulou 2016). Sink mounts have a custom-made padded cavity cut into the base where the artifact sits partially recessed, and can provide support and immobilize fragile artifacts. Also, textiles can be mounted in double-sided storage mounts which allows access to both sides while fully supporting the artifact as it is turned over.

Proven materials for constructing supports include archival grade box board, fluted polypropylene board, high- and low-density

polyethylene or polyolefin foam, cotton twill tape, washed cotton muslin and washed polyester organza, archival grade polyvinyl acetate adhesives, and archival grade low-melt hot glue. Acidic paper materials and unstable plastics should be avoided. Also, where possible, it is ideal to avoid materials that attract static electricity such as plastic bags; this can cause difficulty manipulating loose fiber fragments.

Controlling environmental conditions, including temperature, relative humidity (RH), and exposure to light, is an important step for preventative conservation of fibrous artifacts. Fibrous artifacts are ideally stored in the dark, at low to moderate temperatures, with stable mid-range RH. Light causes chemical breakdowns leading to discoloration, and higher temperatures increase rates of chemical reaction. A widely fluctuating RH causes mechanical breakdown as fibers shrink and swell in response. High levels of RH cause fibers to swell and lose strength, while very low RH embrittles fibers; this response can vary depending on the preexisting acclimation, material type, and the stresses on fibers within the artifact's construction. Additionally, the combination of high temperature and RH levels increases the risk of biological growth such as mold, and pest infestations. While pests may be problematic, preventive treatment using pesticides is not advised; infestations can be effectively managed by freezing artifacts, which can kill all stages of life of insect infestations when done appropriately.

Treatment

Cleaning and drying

Surface cleaning is often necessary to facilitate examination, identification, research, and storage of fibrous artifacts. It is also an important first test to treating a fibrous artifact, as surface dirt and accretions can be hygroscopic, absorbing and retaining moisture at the surface of the artifact, which is potentially damaging. Dry mechanical cleaning is the least invasive and most common form of cleaning; dirt is lifted with a small fan brush, working towards a vacuum nozzle which clears the lifted dirt. The nozzle should be covered with a fine mesh fabric and held at a distance to

prevent uptaking fibers from the artifact itself. In many instances, this is the only cleaning measure required.

Aqueous cleaning is more invasive and a higher risk treatment, and though common for desiccated artifacts in past decades, it is used less often today. Fibers swell and regain flexibility as they absorb water, which severely reduces mechanical strength and may lead to fiber collapse. Aqueous cleaning can also cause colorant bleeding or fading, and loss of important residues. Localized aqueous cleaning may be more appropriate to address unwanted staining, such as using chelating agents to remove iron staining.

Fibers shrink as water evaporates during the drying phase, with potential to permanently distort the artifact. When aqueous cleaning is performed, drying must be gradual to minimize damage. This is achieved by replacing water with solvent in intervals, or freezing wet artifacts to sublimate ice under vacuum (Brooks and Eastop 2011). Similar drying processes are also used on waterlogged artifacts (Senge and Carrlee 2013).

Reshaping

Aqueous methods of flattening and blocking archaeological textiles were once common, though this practice has fallen out of trend. Original creases provide information about how the object was used or buried. While archaeological textiles are routinely unfolded, in many instances the creases and folds are maintained. When artifacts are so distorted that reading the artifact is inhibited, it may be appropriate to relax creases and folds, and reshape the artifact using humidification. This process can be conducted locally or in a humidification chamber using water and/or alcohol vapor for reshaping both flat textiles and three-dimensional fibrous artifacts. Humidification has reduced risks compared to aqueous submersion; however, water vapor causes fibers to swell and increases the potential for biological growth. Alcohol vapor can help fibers regain flexibility without causing swelling and is also a biocide. Once flexibility is regained, artifacts can be coaxed closer to their original

shape. Supports are used to hold the position during drying, which the fibers retain once dry.

Stabilization treatments

Commonly, stabilization of fibrous artifacts requires additional supporting material for strength and overall coherence. These treatments vary based on the needs of individual artifacts and are ideally carried out using methods and materials that allow for future reversal or retreatment. Small localized mends using stitching, ties, or small amounts of adhesive can help regain the integrity of the artifact's structure in areas of partial loss. This can be achieved with minimally and strategically placed mends such as with hair, silk, or nylon filament, long fiber archival paper, or a compatible adhesive. Flat artifacts can be attached to a backing using stitching or specialized adhesives; however, in doing so, one side of the textile is made inaccessible. Consolidation treatments can be carried out on highly fragile objects that are too fragile for basic handling. Because consolidants absorb into the surface, these treatments are essentially irreversible. For waterlogged artifacts, it is necessary to permanently replace water molecules to prevent fibers from collapsing; this has been achieved with polyethylene glycol.

Conclusion

In many instances, a minimal approach is often the smartest and more effective for long-term preservation. Often, poorly executed treatments or treatments using incompatible materials will cause damage to an artifact over time. Before adding a material or adhesive to an artifact, it is necessary to understand the compatibility and long-term effects of the materials. The addition of adhesives, consolidants, and impregnation materials can become problematic for future study and analysis, including DNA analysis and carbon-14 dating. These considerations must be weighed along with the immediate stabilization needs and the artifact when selecting an appropriate conservation treatment.

Conservation of Metals

ALICE BOCCIA PATERAKIS

Japanese Institute of Anatolian Archaeology, Turkey

Introduction

History of archaeological conservation

Archaeologists and chemists were the first professionals to carry out the conservation of archaeological artifacts, which led to the growth of “conservation” as a profession and to the establishment of the “conservator” as a professional who practices conservation of heritage materials. Large industrial metal objects have become part of our archaeological heritage; the preservation of spacecraft and ships is becoming increasingly prominent. Training to be a conservator of archaeological metals involves education in metallurgy, metalworking and manufacturing techniques, metal corrosion, archaeology, art history, analytical methods, and the ethics of conservation.

Corrosion

The greatest challenge presented by metals when it comes to their preservation is their instability and their tendency to revert to the original ores used in their manufacture, through a process called corrosion. Corrosion is largely an electrochemical process involving water and oxygen. Other forms of deterioration include physical damage such as cracking, delamination, and the influence of biological organisms. The preponderance of corrosion and other forms of deterioration depends on the composition of the metal, the method of manufacture and metalworking techniques, the life of the object prior to burial, the burial environment, the environmental conditions after excavation, and the handling and conservation treatments after excavation.

Copper and copper alloys in land burials corrode by forming carbonate, oxide, and chloride compounds sometimes accompanied by calcareous or siliceous encrustations (Cronyn 1990). Copper sulfides are often caused by sulfate-reducing bacteria in anaerobic conditions. Copper sulfide and copper chloride corrosion products are commonly found on marine copper and copper alloys. The copper iron sulfide, chalcopyrite, can form on bronze from sulfate-reducing bacteria, in anaerobic burial conditions. For copper alloys, removal or stabilization of chlorides is the main challenge; with marine objects, this challenge is complicated by marine concretions.

Iron and steel are sensitive to chloride contamination that can accelerate and perpetuate corrosion. Bacteria can contribute to the corrosion of iron and steel: sheath-forming bacteria can cause corrosion through differential aeration, and sulfate-reducing bacteria attack in anaerobic burial conditions, forming black iron sulfide. Iron in seawater forms iron hydroxides, iron chlorides, iron sulfide, and iron oxides (Pearson 1987).

Archaeological silver tends to form stable corrosion products: silver sulfide and silver chloride. Silver sulfide forms on silver from sulfate-reducing bacteria in anaerobic conditions; in aerobic conditions, silver chloride forms. Lead forms lead carbonate, lead oxides, lead chloride, and lead sulfate in aerobic conditions and lead sulfide in anaerobic conditions. These are all considered stable corrosion products that do not contribute to continuing corrosion, although they can hinder legibility. Tin is most commonly found as an alloy in bronze or pewter and forms two types of oxidation products. The formation of lead sulfate on pewter can protect it from further corrosion on the seabed. Gold, as a noble metal, does not corrode unless alloyed with baser metals such as silver or copper. Aluminum alloys are protected by the formation of Al_2O_3 but can be attacked by chlorides if this protective layer fails (Watkinson 2010).

Composite and decorated objects

Composite objects present particular challenges, such as the treatment of waterlogged wooden ships with polyethylene glycol (PEG), which corrodes the iron components. Several forms of decoration on metal artifacts that involve different metals in contact with one another—such as niello, damascening, gilding, and enameling—can present individual challenges for their conservation.

Ethics

Among those international charters dealing with the ethics of preservation of the archaeological heritage, the 1990 ICOMOS Charter for the Protection and Management of the Archaeological Heritage and the 2001 UNESCO Convention on the Protection of the Underwater Cultural Heritage are prominent. The Metals Working Group of the International Council for Museums Committee for Conservation (ICOM-CC) publishes periodic conference proceedings. The trend in conservation has increasingly favored minimal intervention and alteration of the original object, reversibility of conservation materials and methods, and nondestructive methods of investigation and analysis.

Approaches to conservation

It is the shared responsibility of the archaeologist and the conservator to collaborate in decisions regarding the excavation and preservation of archaeological objects. The options to consider include removal from the burial site through excavation and lifting, preservation in situ, and reburial (Watkinson and Neal 2001). Conservation can be carried out in situ as a first-aid measure for removing delicate or difficult objects or as a means of long-term preservation. Proper handling and packing immediately after excavation is vital for minimizing the shock of removal from the burial equilibrium and exposure to dissimilar conditions of temperature, moisture, and oxygen. Once an object is brought to the conservation laboratory, two basic approaches to conservation treatment can be taken: interventive (active) or preventive (passive). Interventive

conservation implies the direct application of conservation materials for the treatment of the object. Preventive conservation involves controlling the environment that surrounds the object either to stabilize it temporarily, until interventive treatment can be carried out, or as a permanent stabilization strategy.

Research and investigation

Research to be carried out before conservation treatment begins includes the identification of the metal and alloys, corrosion products, and causes of corrosion and the technology used to manufacture the metal object. With all metals it is important to ascertain the condition of the object before deciding on a conservation treatment (Cronyn 1990). Numerous analytical techniques are available for examining the morphology, elemental composition, and crystalline structure of corrosion (Dillmann et al. 2013). Electrochemical methods may be used to analyze the surface of metal in conjunction with time-lapse synchrotron X-rays (SR-X-rays). Voltammetry of microparticles (VMP) is an electrochemical technique for the identification of metals and corrosion products and for mapping corrosion products on the artifact. Laser-induced breakdown spectroscopy (LIBS) is useful as a nondestructive method for the elemental analysis and depth profiling of archaeological metals. Radiography using X-radiography and 2D or 3D X-ray computer tomography of metal objects prior to cleaning can reveal considerable information, including the extent of mineralization, the location of the original surface, decorative elements, and evidence of manufacture. Documentation of all research, investigation, and treatment is a necessary part of the conservation process for which databases are used.

Stabilization

The term *stabilization* is used to denote the retardation of deterioration with the goal of halting deterioration by any number of interventive or preventive conservation means. By mitigating the physical, chemical, and biological factors of deterioration, the conservator attempts to achieve stabilization.

Interventive conservation

There are numerous interventive means by which one can stabilize and conserve corroding metal artifacts. Those considered here are cleaning, chloride conversion, chloride removal (desalination), corrosion inhibitors, and protective coatings.

Cleaning

The cleaning of metal artifacts may be carried out by mechanical and/or chemical means. Initial cleaning involves investigative work to ascertain the extent and location of corrosion, the location of the original surface and surface detail, and the physical condition of the object.

Mechanical cleaning Mechanical cleaning is carried out with small hand tools such as scalpels, vibrotools, cavitrons, glass bristle brushes, and grinding tools using illuminated magnification. Air-abrasive techniques using glass bead microspheres, walnut shells, sodium bicarbonate, and aluminum oxide are sometimes used to clean metals. Laser cleaning with carbon dioxide lasers, Nd:YAG (neodymium-doped yttrium aluminum garnet) lasers, and excimer lasers and TEA-CO₂ (transversely excited atmosphere carbon dioxide) laser ablation have been applied to archaeological metals. Ultrasonic cavitation can enhance chemical cleaning by dislodging residues when used with caution.

Chemical cleaning Acids, alkalis, complexing agents, and chelating/sequestering agents are used to clean archaeological metals. Inhibitors and surfactants may be added to promote cleaning. The removal of residual chemicals must be carried out following cleaning.

The cleaning agents for calcareous encrustations and corrosion on copper and copper alloys include alkaline Rochelle salt (50 g/l sodium hydroxide and 150 g/l sodium potassium tartrate), alkaline glycerol (150 g/l sodium hydroxide and 40 ml/l glycerol), citric acid (sometimes buffered with ammonium hydroxide or thiourea), Calgon (150 g/l), formic acid, sulfuric acid, sodium hydroxide, ammonium hydroxide, ammonium tricitrate, ethylene

diamine tetra-acetic acid (EDTA) (disodium or tetrasodium salt), sodium diethylene triaminepentaacetic acid (DTPA), and sodium tripolyphosphate (Scott 2002). The trend from the twentieth century to the present day involves the gradual abandonment of “stripping” metals of corrosion in favor of retaining the patina whenever possible.

Ethylene diamine tetra-acetic acid (EDTA: disodium salt) and weak acid solutions will remove lead carbonate from lead objects. Ion-exchange resin has been found useful for the removal of lead chloride and carbonate from lead and pewter objects. Tin coatings on copper alloys require mechanical cleaning, as they are susceptible to alkalis and acids.

Conversion of chlorides

In the majority of cases the conversion or removal of chlorides is necessary to prevent further corrosion of copper, copper alloys, and iron. Conversion coatings interact with the corrosion to form stable corrosion, as in the application of sodium sesquicarbonate to cuprous chloride to form the stable cuprite (copper oxide), which can also generate undesirable corrosion products.

Desalination

The process of removing chlorides from a metal artifact through immersion or with poultices is called desalination. The removal of chlorides may be carried out through one out of several methods, and the release of chlorides can be monitored.

Water washing The solvation and solubility of chlorides varies; iron chlorides tend to be more soluble than other chlorides, such as copper chloride and silver chloride. Removal of chlorides during immersion in water has been improved through the introduction of alkaline substances.

Alkaline washing Alkaline solutions that increase the solvation and removal of chlorides while acting as corrosion inhibitors are especially useful for iron, preventing further corrosion (Watkinson 2010). Sodium hydroxide is typically used for this purpose.

Subcritical high-pressure alkali treatment

Stabilization in subcritical fluids with 0.5 percent (w/w) sodium hydroxide solution at 180 °C was found to be faster than with a 0.5–1.0 percent sodium hydroxide solution (with or without cathodic polarization) for removing chloride from marine iron, as in the case of the American Civil War *Hunley* submarine (Dillmann et al. 2013).

Complexing agents

Aqueous ethylene diamine solutions (5% v/v and 11.5 pH) have been used to extract chlorides from iron with reportedly less success than aqueous solutions of sodium hydroxide (2%). Aqueous acetonitrile complexing reagent has found use for the removal of chlorides from marine bronze, although it can disrupt the cuprite layer.

Chemical reduction

The aqueous extraction of chlorides from land and marine iron has been greatly improved with the alkaline sulfite reduction method since the 1970s. This method involves immersing the iron object in a solution of sodium hydroxide and sodium sulfite of varying concentrations, at temperatures ranging from 50° to 70°C (Scott and Eggert 2009).

The alkaline dithionite (40 g/l sodium hydroxide and 50 g/l sodium dithionite) reduction method was originally devised for bronze from saltwater sites but can also be used on bronze from land sites.

Electrolytic reduction

Electrolytic reduction involves making the object to be cleaned the cathode, which is immersed, with an anode, in an electrolyte to which an external electric current is applied. The electrolytic reduction of copper alloy objects using an externally applied current through a sodium hydroxide, sodium carbonate, or sodium sesquicarbonate electrolyte will alter or remove the patina. Using distilled water as the electrolyte and platinum or gold as the anode, an electric current may be established by connecting both electrodes to one another and to a milliamperemeter, in which case the patina is not removed. Alternatively, electrolysis may be applied locally, to areas of bronze disease, with an electrolytic pen and without immersing the object.

Electrolytic reduction is used for iron from both land and marine sites. Electrolytic reduction with sacrificial anodes can be carried out in situ for iron objects in suitable conditions.

A form of electrolytic reduction, consolidative reduction, may be used to strengthen heavily corroded silver. Consolidative reduction involves the steps of reducing, dissolving, and then depositing the reduced silver using partly rectified current.

As in the case of silver, electrolytic reduction may be used to remove the corrosion from lead, and consolidative reduction with partly rectified current may be used to strengthen severely deteriorated and weakened lead objects and to restore the surface decoration. Chlorides have been removed from aluminum alloy aircraft through electrolysis.

Electrochemical reduction

Electrochemical reduction makes the object to be cleaned the cathode and puts it in contact with a more noble metal, used as anode, in an electrolyte that establishes a potential difference without an externally generated electric current, thereby reducing the corrosion while oxidizing the anode.

Hydrogen reduction

Hydrogen reduction has been used in Sweden on the Wasa iron artifacts and more recently for large marine iron objects, such as the cannons on the *Mary Rose*. The Swiss National Museum in Zurich has developed low-temperature (50° to 200°C) hydrogen plasma reduction, which is safer for the operator and avoids microstructural changes to the metal.

Monitoring the removal of chlorides

Measuring chlorides that are released during desalination can be carried out with simple titration kits, electronic chloride meters, and chloride-specific ion meters. More sophisticated analytical means include ion chromatography and inductively coupled plasma mass spectrometry (ICP-MS). Determining the amount of chloride remaining in the object can be more challenging and destructive to the object.

Corrosion inhibitors

Blocking chlorides with chemical corrosion inhibitors through either local application or immersion is one means of stabilizing metal. Common corrosion inhibitors for copper and copper alloys are benzotriazole (BTA), 2-amino-5-mercapto-1,3,4-thiadiazole (AMT), and a combination of BTA and AMT. Locally applied corrosion inhibitors for copper alloys include silver oxide, silver nitrate, and zinc powder. For iron and steel, the most common corrosion inhibitors have been tannins. Triethanolamine salt of an acrylamido carboxylic acid (Hostacor IT) and phosphates added to PEG solutions during the treatment of waterlogged wood with iron components have protected the iron from corrosion. Self-assembled monolayers (SAMs) are considered state-of-the-art corrosion inhibitors for some metals such as silver. Carboxylates, especially sodium decanoate, showed good results on heritage objects and have the added advantage of reversibility (Dillmann et al. 2013). BTA and carboxylates show promise as corrosion inhibitors on zinc and brass.

Protective coatings

Coatings are often applied to protect metal objects from moisture and oxygen after cleaning and desalination. Microcrystalline wax, Incralac (a methyl methacrylate copolymer with BTA), Paraloid B-72, B-44, and B-48 N methyl methacrylate copolymers, and ORMOCERs (inorganic-organic copolymers) are among the coating materials used today. Organosilane-based coatings and solgels (3-mercapto-trimethoxysilylpropane; Prop-SH solution) have been used for copper alloys. Conducting polymer films such as poly (3-amino-1,2,4-triazole) have been found to protect silver, copper, and copper alloy artifacts. Sodium carboxylate SAMs have been used successfully to protect iron, copper, zinc, and lead artifacts from corrosion and present the advantage of reversibility (Dillmann et al. 2013).

Preventive conservation

Preventive conservation of metal objects involves controlling the moisture, temperature, and oxygen levels of their environment. Preventive conservation of underwater metals can take place while the object is submerged in situ or immersed in a stabilizing solution in the conservation laboratory.

Preventive conservation instead of, or preceding, interventive conservation

When numerous metal objects are excavated and the availability of conservation hours is limited, objects must often be stored for long periods of time before they can be examined, cleaned, inventoried, and so on. In such cases preventive conservation is particularly important for archaeological bronze and iron, since chlorides from burial render these metals especially sensitive to ambient moisture and oxygen. Small iron and bronze objects from land sites may be stored in desiccated or anoxic conditions, thereby being spared any further deterioration. The Revolutionary Preservation System (RPS) of anoxic and desiccated storage has been used with success for archaeological metals in Turkey (Paterakis and Hickey-Friedman 2011).

Iron that is contaminated with chlorides from land and underwater sites may be stored in solutions of sodium sesquicarbonate and sodium hydroxide or sodium sulfite in order to retard corrosion until desalination can be carried out. The stability of iron may be monitored by measuring the corrosion potential (E_{corr}) of the artifacts in sodium sesquicarbonate and sodium hydroxide solution (Scott and Eggert 2009). The cathodic protection of marine iron involves the use of sacrificial anodes or impressed current. Monitoring the corrosion indicator value by periodically measuring the pH and E_{corr} will determine which objects are most at risk and what is the end point of treatment, that is, when most chlorides have been removed (MacLeod 2014).

Preventive conservation following interventive conservation

For the safe display and storage of archaeological metals after interventive conservation, knowledge of the most suitable materials for storage and display and of the acceptable environmental parameters (levels of temperature, relative humidity, oxygen, volatile organic compounds, and other atmospheric pollutants) is necessary. Environmental remediation as a form of preventive conservation is necessary for the safe display and storage of metal objects both in the short term and in the long term. Preventive conservation after interventive conservation is especially important if chemical stabilization is not entirely successful (see previous section and Paterakis and Hickey-Friedman 2011). Other means of preventing corrosion include sorbents, scavengers, and vapor-phase inhibitors placed in the storage or display case and vapor-barrier films for case surfaces.

Conservation of Mosaics

THOMAS ROBY

Getty Conservation Institute, USA

Definition of mosaics

Mosaics are a type of architectural surface decoration which developed in the Hellenistic and Roman periods and continued through the Byzantine and even early Islamic periods. Mosaics normally decorate floors, but the technique was used for wall surfaces and vaults as well in both private homes and public buildings.

Mosaics are commonly considered to be those pavements that use small cut cubes (*tesserae*) of stone, ceramic, or glass inserted in a bedding layer of lime (calcium hydroxide), supported by a foundation of several layers of lime mortar (*nucleus* and *rudus*) and a stone rubble base or leveling course (*statumen*). The Latin names for these support layers have come down to us through the Roman architect and author Vitruvius. Miniature mosaic panels, using extremely small tesserae (*opus vermiculatum*), were also used as portable decoration or for insertion centrally within larger pavements (*emblemata*).

Other types of ancient pavements can be grouped together under the term “mosaic,” such as pebble pavements, a precursor to cut tesserae pavements, or pavements composed of slabs of decorative stone, often marble, cut into geometric shapes (*opus sectile*), or of a combination of both tesserae and stone slabs (*opus scutulatum*).

Conservation challenges and approaches

The conservation of these pavements, whether in situ as a complete composite, layered structure, linked to the architectural structure it adorns, or within museum collections as a detached surface, presents numerous and varied challenges. The surface of an in-situ mosaic is located at the

interface of a building and the surrounding environment and is therefore particularly exposed to often rapidly changing external conditions and forces. At the same time, an in-situ mosaic is part of a building system, with foundations that link it to the below-ground environment and its changing conditions as well. The dynamic natural environment surrounding an in-situ mosaic above and below ground is the cause of many different mechanisms of deterioration which can negatively impact the condition of a mosaic and its constituent porous materials over time.

The challenge of conserving mosaics whose tesserae surface (*tessellatum*) has already been detached and removed from their architectural context on site is often related to the choice of modern materials used to provide a new support for the *tessellatum*. The environmental conditions within a museum or a storage facility, while generally more controlled than an open-air situation on site, can also contribute to the deterioration of a detached mosaic regardless of the type of support or whether the mosaic has been provided with a new modern support. But the operation of detaching a mosaic from its bedding layers destroys part of the bedding layers and can provoke the loss of or damage to the tesserae themselves to various degrees, depending on the detachment technique used and the skill of the operators.

The conservation of mosaics consists of a variety of activities, some of them preventive measures aimed at controlling the environment of a mosaic in order to diminish the causes of deterioration and thereby slow its rate of deterioration. Such measures include the construction of a shelter, and access barriers and walkways to prevent visitors from walking directly on mosaics, as well as reburial or seasonal protective coverings. Other activities are remedial interventions to restore structural stability to a mosaic by means of adding or applying new materials to replace lost or damaged original constituent materials.

The methods and materials used to conserve mosaics, whether preventive or remedial, have evolved over the centuries, especially in recent decades as a more scientific methodology and

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0121

conservation ethic has been adopted, favoring an in-situ, preventive conservation approach over removing mosaic surfaces to be preserved in a museum or replaced in situ on a new support. The current approach reflects the additional cultural value that a mosaic is considered to possess if it is preserved within its original architectural context and if its original constituent materials are preserved as much as possible, while limiting the addition of new material. In this way, the authenticity of the mosaic is preserved, as opposed to restoring the original decorative image (Roby 2006).

The current approach is also more holistic. Whereas in the past, the more valued figurative component of a pavement might have often been removed from its surrounding geometric decoration, a pavement would now be conserved in its entirety. In addition, the conservation of a collection of mosaics within an entire building or an entire site would be addressed rather than favoring the conservation of its figurative mosaics over nonfigurative ones or of certain types of mosaic pavements over others.

The present conservation methodology for mosaics and other categories of heritage materials includes an initial phase of study and assessment before carrying out a conservation intervention, all of which are thoroughly documented. Interventions are then followed by monitoring of condition and maintenance activities as needed.

A conservation assessment of a mosaic or collection of mosaics should consider three aspects: its significance or cultural importance within a particular region; its condition; and its degree of exposure to environmental and human factors of deterioration. These different aspects can then be assigned a rating for each mosaic, and combined to achieve an overall priority rating for intervention or more detailed study when considering a large collection of mosaics (Roby et al. 2017).

An assessment of condition should normally be carried out by a conservator or conservation technician and can be done at three levels: an initial rapid survey to obtain basic data and set priorities; followed by a detailed condition survey in preparation for planning and executing conservation treatments; and possibly a specialist survey consisting of material analysis of constituent materials and agents of deterioration,

hydrological and/or geological mapping, collection of environmental data, and so on (Stewart 2014).

An important component of assessing condition is determining whether deterioration is active or ongoing, what the rate of deterioration is, and its causes. This will be important in determining priority of conservation action. To do this, it may be necessary to monitor the condition of a mosaic over time, rather than rely on a single inspection.

Deterioration

Mosaics are subject to deterioration from various causes throughout their history, from ancient mechanical damage due to wear and impact, through burial and subsequent growth of tree and plant roots and burrowing animals, to environmental exposure upon excavation (see DETERIORATION OF MOSAICS).

Remedial interventions on in-situ mosaics

The aim of conservation interventions on mosaics is to reestablish their structural stability. This is achieved by trained conservators and technicians using lime-based mortars to carry out a variety of repairs: filling areas of loss of tesserae or original mortar (fills of lacunae and of interstices or joints between tesserae), protecting broken edges of mosaic (edging repairs), re-adhering bedding layers which have become partially separated (injection grouting of voids), and re-adhering loose tesserae to their bedding in their original position (resetting of tesserae).

In the past, and still in some cases, excavated loose tesserae or even modern tesserae have been used to fill areas of lost tesserae, but this is normally not practiced because it compromises the authenticity of the mosaic. Instead, mortar is generally used, while paying attention to its surface color and texture, in order to reduce the visual impact of the mortar within the mosaic. This is done through the careful selection of mortar aggregates such as sand and crushed stone, and sponging of the mortar surface to remove

Figure 1 Lacunae infilling with lime mortar.

lime and to make the aggregates more visible (Figure 1).

The structural stabilization of mosaics through injection grouting of voids below the surface, generally along the interface between bedding layers, is a relatively recent advance in the treatment of in-situ mosaics (see *GROUTING IN CONSERVATION*). The introduction of this technique has had the most impact on reversing the trend away from the routine detachment of mosaics and relaying them on a new support. In the past, complete detachment was the response to the common deterioration phenomenon of localized loss of adhesion between the bedding layers of a mosaic, as there were no known alternative treatments.

The other significant recent advance in treatment methodology has been the move from the use of cement-based mortars for repairs to the use of lime-based mortars. Such mortars can be made of lime putty or natural hydraulic lime (NHL) or a combination of the two, depending on the type of treatment and the mortar characteristics required. To be effective, the application of lime mortars requires training, and care needs to be taken to avoid the rapid drying out of such

mortars before setting of the lime has occurred. Portland cement-based mortars were commonly used, but are not considered appropriate because of their excessive mechanical strength and salt content which can accelerate the deterioration of the original ancient lime mortars and make its removal in the future very difficult to achieve without damaging the adjacent original materials.

Cleaning is an important component of stabilization interventions because it is necessary to have mosaic surfaces cleaned of dirt and microbiological growth for the mortar repairs to adhere and remain attached to the mosaic. Cleaning is normally carried out using mechanical means such as brushing with soft bristle brushes and some specialized tools such as scalpels and dental pics, together with limited amounts of clean water, often applied by hand pump sprayer and removed by sponge. This can be done effectively without resorting to chemical solutions and biocides. Cleaning is also carried out as part of routine maintenance to remove accumulated wind-blown soil and sand and to remove microorganisms, both of which will promote the growth of plants.

Remedial intervention of mosaics previously detached and relaid in situ

Due to the accelerating deterioration of the thousands of mosaics detached and relaid on site on reinforced concrete during most of the last century, conservation attention has recently focused on saving these mosaics. Such mosaics pose even more of a challenge than conserving in-situ mosaics as the options for their protection are more limited. Reburial and protective shelters are not long-term options if the reinforced concrete has been exposed already for many years. There are two conservation options for such mosaics. The first is to remove the corroded rebar if it is causing damage to the mosaic. This can be done by localized facing of the mosaic surface and temporarily removing the detached part of the *tessellatum*. After removing the corroded rebar underneath, the *tessellatum* is relaid on a new bedding of cementitious mortar.

While this intervention can remove the immediate cause of the deterioration, the long-term solution to conserving mosaics relaid on reinforced concrete panels on site can be to remove the entire support panel and relay the detached mosaic on new bedding layers of lime mortar, similar to the original foundation stratigraphy. This is a difficult and costly operation, however, as removing the concrete can provoke damage to the original tesserae which are weaker than the concrete to which they are strongly adhered. In addition, the original detachment of the mosaics in sections may have led to the loss of rows of tesserae along their edges which could then make their correct relaying in relation to the other panels conjectural. Facing the mosaic and removing it in sections to a laboratory where the concrete support panel is removed, constructing a new foundation of layers of lime-based mortar and relaying the *tessellatum* on them in their original location, are all operations requiring considerable skill and resources, but only in this way can the mosaics be preserved and protected in situ for the long term.

Preventive measures for conserving mosaics in situ

In order to respond to the challenges posed by the exposure and neglect of mosaics on sites, both those on their original foundations and those detached and relaid on reinforced concrete, the lack of financial and trained human resources to address them means that preventive measures, and in particular reburial for those on their original mortar layers, need to be employed (see PREVENTIVE CONSERVATION IN ARCHAEOLOGICAL SITES). Reburial is the most cost-effective means of preventing mosaic deterioration, whether it be for the short or long term (Roby, Alberti, and Ben Abed 2014). However, to be effective it should be designed using appropriate materials of sufficient depth and adequate containment to create a stable environment, and then properly maintained to control growth of vegetation in particular (Stewart 2004) (Figure 2).

Separation membranes are frequently used as part of a reburial design, especially in contact with the mosaic, as a horizon marker and to facilitate reexcavation. However, if the membrane is impermeable it can have negative consequences, as the membrane will promote root growth and other biological activity under it. Geotextiles have been increasingly used in reburials as a separation membrane in recent decades, but they can prevent intimate contact between the mosaic surface and the fill materials and thereby inhibit the free movement of water from the substrate up, which is not characteristic of an effective reburial.

In addition to recreating a more stable environment to slow down deterioration, reburial prevents the mechanical damage resulting from visitors walking directly on a mosaic. If, however, the mosaic is selected to be presented to the public, other means of preventing the public from walking directly on it should be created, either by erecting access barriers beside it or by constructing walkways over it.

The construction of a shelter is a commonly used preventive measure to slow mosaic deterioration on sites by reducing the effects of wetting and drying cycles and temperature fluctuations. Shelters can, however, exacerbate certain

Figure 2 Reburial of mosaic with two fill materials separated by geotextile.

Source: Photo: Christopher Sprinkle. © 2015 The J. Paul Getty Trust. All rights reserved.

environmental conditions which accelerate deterioration if they are not designed to achieve certain performance criteria. Shelters are more costly to design and construct than reburials and they will often require more maintenance, which can make sheltering a less feasible preventive measure in many contexts with limited resources. Therefore, the decision to shelter or to rebury should be considered in the context of long-term site-wide planning based on a site assessment and prioritized action plan.

Such site-wide planning should include a maintenance plan based on periodic inspections to monitor conditions and subsequent maintenance as needed. Maintenance activities for mosaics on site will include cleaning of the *tesselatum* surface, localized stabilization treatments with lime mortar, and vegetation removal. In addition, maintenance and repairs of all preventive measures such as reburials and shelters will need to be part of a maintenance plan that takes into account the site resources and management context.

Conservation of Polychrome Natural and Architectural Surfaces

LESLIE RAINER

Getty Conservation Institute, USA

Overview

The term “polychrome natural and architectural surfaces” encompasses a wide array of materials and techniques used to embellish the natural and built heritage. This array extends to pictographs in natural settings and to polychrome architectural surfaces such as wall paintings, murals, bas-reliefs, stuccowork, and mosaics—in archaeological, historical, and contemporary contexts, on interior or exterior walls, ceilings, vaults, and floors.

Significance and context

Polychrome natural and architectural surfaces are by definition immovable heritage. They are a visual record of beliefs, lifestyles, and technologies, and often signifiers of social status. As integral elements of natural formations or architectural ensembles, polychrome surfaces form the protective skin of the structure and the presentation surface. They can have aesthetic, religious, or cultural value in and of themselves and can represent the defining feature of a site or structure or be part of a larger cultural landscape.

Whether the polychrome surface is in an archaeological, historical, or contemporary context determines to some extent the approach to conservation. Typically, in the case of pictographs (Figure 1) and other rock art, the environment and the landscape (see ENVIRONMENT AND LANDSCAPE) of the work are addressed in order to protect not only the polychrome surface as a work of art but also its context and function as an integral feature of the landscape (see HERITAGE

AND LANDSCAPES). In an archaeological context, the polychrome decoration imparts information about past societies and is part of the archaeological record (see ARCHAEOLOGICAL RECORD). Tool marks and traces of painting technology, as well as any signs of cultural practice, are as important as the legibility of the decoration or the painted scheme (Figure 2). In the case of historical decorated surfaces, if the integrity of the decorative scheme is of importance to the architectural ensemble (Figure 3), then the conservation treatment may include restoration of the decoration where that is missing. For polychrome surfaces such as contemporary murals and polychrome decoration carried out in the context of a living tradition (Figure 4) or when the artist is still living, artists may participate in the conservation process, renewing and in some cases repainting the decoration.

Due to the different contexts and varied types of substrates, plaster, and paint materials, the conservation of these surfaces is complex and must be addressed as an integral part of the larger natural or architectural system to which the surfaces belong. In a broader sense, the preservation of polychrome natural and architectural surfaces is tied to the cultural context in which they were created, and their long-term preservation depends on the local community and other stakeholders—and their awareness of and engagement with their own heritage (see HERITAGE ETHICS).

Deterioration

The deterioration of polychrome surfaces is often linked to larger conservation issues of the formation or structure. This may be particularly problematic in the archaeological context, where natural and architectural surfaces are often exposed to the elements. Causes of deterioration can include environmental influences, natural disasters (e.g., seismic activity, flooding), and human intervention, whether unintended or intentional, and lack of maintenance.

Typical deterioration phenomena include, but are not limited to, structural failure of the substrate, impact and abrasion, exfoliation, spalling, decohesion, and erosion (see *EROSION*) of the substrate; delamination and decohesion of plaster and paint materials; flaking of paint; salt efflorescence; biodeterioration; and alteration of original and intervention materials. Given that the natural or architectural systems of which polychrome surfaces are an integral part are complex, deterioration mechanisms may also be due to a combination of factors, which must be systemically addressed in order to ensure the long-term preservation of the natural or architectural ensemble.

Conservation approach

The conservation approach to polychrome natural and architectural surfaces has developed over time. In the past, decorated surfaces were often detached from their support, removed from their context, and treated as movable objects. However, it is now recognized that a polychrome natural or architectural surface is an integral part of the formation or architecture for which it was conceived (Mora, Mora, and Philippot 1984). With the trend of preservation of cultural heritage in situ since the 1960s, current practice takes a holistic approach to the conservation of polychrome natural or architectural surfaces as parts of a larger system, whether natural or architectural. No painted surface can be conserved without taking into consideration the conservation issues of the site, the structure, or the landscape. The conservation of these surfaces depends on an interdisciplinary team of conservation professionals, composed of conservators of architectural surfaces and/or rock art, architects, engineers, scientists, and documentation specialists, to address the complex and challenging conservation issues with which they are presented.

More broadly, effective management systems are essential to the long-term preservation of polychrome natural and architectural surfaces; and should actively involve key stakeholders—especially traditional owners, caretakers, site managers, building owners, local communities, and governmental bodies—in

order to provide adequate support for heritage, in all aspects of preservation and conservation (Agnew et al. 2015).

A management plan (see *HERITAGE MANAGEMENT*) for the site or building should normally be drafted and implemented prior to addressing conservation issues of the surface itself, except in rare circumstances when the surface is endangered, and must receive urgent treatment, as in the case of natural flooding, or the building of dams in areas with significant polychrome surfaces. A successful management plan will consider public and political awareness of the vulnerability, uniqueness, value, and significance of the polychrome surface and its support and context (Agnew et al. 2015).

A comprehensive conservation plan (see *CONSERVATION PLANS*) for the natural site, structure, or wall and for the polychrome surface and support should consider larger site issues such as drainage or site protection, and structural problems, as well as passive measures and remedial treatments of the polychrome surface and support. This is critical in order to ensure the long-term sustainability of conservation efforts.

Once larger site and structural issues have been addressed, the methodology currently followed in the conservation of these surfaces is based on a series of overlapping and iterative steps, which begin with background research, environmental monitoring, diagnostic investigation, and condition assessment to develop passive measures and remedial treatments. Following implementation of conservation measures, posttreatment monitoring and maintenance should be planned and carried out. All the steps taken in the conservation process, should be fully documented.

Background research

Background research aims to gather information related to the physical history and use of the natural or cultural site, architectural complex, building, or wall. Archival research, the compilation of historical photographs, and oral histories are some of the means by which information about the surfaces and the site may be obtained. Information recorded should include the physical history and use of the site, the technique

of execution, and previous interventions. Comparative studies of similar sites and surfaces, related treatments, interviews with living artists, custodians, or other stakeholders, and examples of ongoing cultural and artistic practice can add to the background research.

Environmental monitoring and climate improvement strategies

Environmental monitoring is used to better understand current conditions and their possible impact on the site, structure, and surface in order to develop appropriate climate improvement strategies. Depending on scope, resources, and needs, this work can be limited to a basic monitoring of the temperature and of the relative humidity or it can be more sophisticated, in which case it might involve the monitoring of more factors: ground moisture, moisture movement inside of walls, surface temperature of walls, air flow, solar radiation, and other site-specific environmental conditions. Data collected from environmental monitoring should be evaluated with respect to the specific deterioration patterns of the polychrome surface, so that environmental causes of deterioration may be determined and appropriate mitigation strategies may be developed accordingly.

Diagnostic investigations

Analytical imaging (see IMAGING) and scientific analysis of original and intervention materials and deterioration products aid in the understanding of the original technique of execution, past treatments, and causes and mechanisms of deterioration of polychrome natural and architectural surfaces.

Analytical imaging includes a range of techniques that is expanding rapidly as technology advances. Currently, techniques such as multispectral imaging (see MULTISPECTRAL AND HYPERSPECTRAL IMAGING OF ARTWORKS), digital image enhancement, reflectance transformation imaging (RTI) (see REFLECTANCE TRANSFORMATION IMAGING (RTI) IN CONSERVATION), photoluminescence of Egyptian blue (see

PHOTOLUMINESCENCE OF EGYPTIAN BLUE) and other pigments, and other imaging techniques can provide information on the composition of paint and plaster materials, the technique of execution, the presence of coatings, and superimposed imagery, which are otherwise difficult to identify. Infrared thermography (see IR THERMOGRAPHY and THERMOGRAPHY), laser speckle interferometry, endoscopy, and radar (see RADAR) are valuable tools for detecting voids behind the surface and anomalies in the stratigraphy of the plaster and substrate.

Today, standard noninvasive analytical techniques include portable X-ray fluorescence, portable Fourier-transform infrared spectroscopy, and fiber optic reflectance spectroscopy (FORS) to identify the materials of the polychromy.

Minimally invasive sampling can provide more precise information than noninvasive techniques. Gas chromatography–mass spectrometry (GC-MS) (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) and high performance liquid chromatography (HPLC) (see HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC)) can be used to identify pigment binders (see PIGMENTS AND BINDERS) and organic materials, while ion chromatography may be used for the characterization of salts. Scanning electron microscopy (see SEM-EDS AND MATERIAL ANALYSIS), optical microscopy (see OPTICAL MICROSCOPY), microchemical testing (see MICROCHEMICAL TESTS IN CONSERVATION), polarized light microscopy, and ultraviolet fluorescence microscopy can be used for the characterization of materials and stratigraphy. Other techniques such as X-ray diffraction (XRD), Raman spectroscopy (see RAMAN SPECTROSCOPY IN CONSERVATION), and laser-induced breakdown spectroscopy (LIBS) (see LASER-INDUCED BREAKDOWN SPECTROSCOPY (LIBS)) can assist in the characterization of constituent materials (see CHARACTERIZATION OF PIGMENTS).

Condition assessment

A condition assessment documents specific conditions of the substrate (natural rock, earth, masonry, wood, plaster), paint, and surface and

should be carried out to better understand current conditions, original technique of execution, previous interventions, and change over time. Conservation documentation (see CONSERVATION DOCUMENTATION) includes recording in graphic, photographic, and written formats and is combined with background research, results of environmental monitoring, and diagnostic investigations aimed at fully understanding materials, conditions, and environmental factors that affect the site, structure, and polychrome surface in order to develop conservation strategies at all levels.

Conservation planning and implementation

On the basis of the condition assessment, which includes environmental monitoring and diagnostic investigations, a conservation plan is developed. This plan must take into consideration sitewide issues, environmental factors, and structural problems as they relate to the polychrome surface. Passive measures and remedial treatments are then developed and implemented. The principles of conservation should be minimal intervention, compatibility of conservation materials with the original materials, stability of conservation materials, and reversibility or retreatability.

Passive measures

Passive and preventive measures may include sheltering, controlling environmental conditions, and, in some cases on archaeological sites, reburial.

Remedial treatments

Remedial treatments may include structural stabilization of the support; plaster stabilization; salt reduction or removal (desalination); reduction or removal of unstable or damaging previous interventions; surface consolidation; readhesion of flaking paint; filling of losses; bioremediation;

surface cleaning; and aesthetic reintegration. Prior to implementing remedial treatments, treatment testing is carried out on mock-ups in the laboratory or in the field. If laboratory-based testing is carried out, further field testing is recommended to verify the feasibility of specific treatments on site.

Structural stabilization

Structural repairs are necessary in the case of roof leaks, capillary rise, structural cracks, poor drainage, and other damage to the site, the structure, or the wall. If structural stabilization will impact the polychrome surface, proper protection should be provided during the structural work.

Plaster stabilization

Voids, cracks, and delaminations of plaster layers have in the past been stabilized with anchors and pins used to physically reattach the plaster to the substrate. Since the 1980s injection grouting (see GROUTING IN CONSERVATION) has typically been used to stabilize plasters, mosaics, and wall paintings in situ. Custom-mixed and commercial grouts have been developed for architectural surfaces. Most are aqueous grouts, but some nonaqueous grouts have also been tested and used in the field. The selection of an injection grout should consider specific properties of the original material and the nature of the void, crack, or delamination to be treated (Biçer-Şimşir and Rainer 2013).

Surface consolidation

Powdering stone, plaster, preparation and/or paint layers should be consolidated in order to reinstate the integrity of the decohesive material. Inorganic mineral consolidants (see MINERAL INORGANIC TREATMENTS) and organic resins have typically been used for surface consolidation. Recently the development of nanomaterials (see NANOTECHNOLOGY AND NANOSCIENCE IN CONSERVATION) for consolidation has broadened the range of suitable materials for surface consolidation. Consideration should be given to the selection of the material, as a film-forming consolidant can create a moisture-impermeable layer

over the polychrome surface, which may lead to unanticipated damage over time, particularly in an uncontrolled environment with fluctuating temperature and relative humidity.

Readhesion of flaking paint

Readhesion of flaking paint requires an appropriate adhesive, which is introduced behind the paint flake. This operation differs from surface consolidation, as it aims to reinstate the adhesion between two intact layers and should not remain on the surface. Conservation adhesives include a wide range of materials, from natural inorganic and organic materials to various synthetic polymers (see *POLYMERS IN CONSERVATION*).

Filling of losses

Typically, losses to earthen-, lime-, or gypsum-based plasters are filled with (repair) mortars similar in composition to the original plaster. In current conservation practice, depending on the site context, losses are often filled to a level slightly below the surface, to distinguish the fill material from the original fabric.

Bioremediation

Bioremediation is necessary when there is active or dormant biogrowth in, on, or around the polychrome surface. Preventive measures can be taken and commercial chemical treatments are currently used; however, essential oils for the treatment of biogrowth are now also being used on stone and are a potential biocide treatment for polychrome surfaces.

Surface cleaning

In many cases, surface cleaning is performed to reinstate the legibility of the decorative scheme and to remove potentially damaging surface accumulations and previous surface treatments (e.g., previously applied and degraded varnishes or surface consolidants). Cleaning techniques can be categorized as dry (e.g., dusting, dry cleaning sponges, and erasers), aqueous (free liquids or gels; see Wolbers 2000), solvent (pure solvents, solvent mixtures, and gels), enzymatic (developed

for the removal of specific materials), and laser (these use a variety of wavelengths; see *LASER CLEANING*).

Aesthetic reintegration

There are many approaches to aesthetic reintegration, depending on the context of the work of art. In current conservation practice, reintegration or inpainting is often minimal, particularly in the case of archaeological surfaces, which have great evidentiary value. With regard to polychromy on natural surfaces such as pictographs, where the superposition of design provides important information on the chronology and cultural significance of the work of art, inpainting is usually not done. On historical painted decoration, it may be important to reinstate the integrity of the architectural scheme, and reconstruction may exceptionally be desirable (Mora, Mora, and Philippot 1984). In the context of living traditions and contemporary murals, when the artist is still living, conservation may take its cue from the artist(s) who created the painted surface, and they may participate in the conservation process, renewing and in some cases repainting the decoration. Inpainting techniques (see *INPAINTING*) have been developed in different schools, regions, and countries. Specific techniques include chromatic reintegration, pointillism, and mimetic inpainting. Stable inpainting materials should be used to avoid changes in appearance or in properties over time. Reversible materials should be used whenever possible to facilitate later retreatment.

Posttreatment monitoring and maintenance

Posttreatment monitoring and maintenance are advisable in order to ensure the long-term preservation of the site, structure, and surface. Monitoring can be carried out using a number of methods including graphic, photographic, and written formats. Maintenance should be performed by trained technicians or by conservation professionals.

Documentation

Conservation documentation (see CONSERVATION DOCUMENTATION) is an integral part of the conservation process. It can be carried out in written, photographic, and graphic form. Laser scanning (see LASER SCANNING) is also used. All stages and aspects of the work should be recorded: conditions, technique of execution, treatment, sample collection, and posttreatment monitoring. Documentation is a valuable tool for the analysis and interpretation of conditions and of change over time and serves as a reference for future conservation needs.

Graphic documentation, too, is often used for recording polychrome surfaces. It can be carried out digitally or by hand, to map conditions directly onto a tablet, on paper or on acetate sheets over drawings, photographic, photogrammetric, or stereophotogrammetric base maps (see PHOTOGRAMMETRY AND STEREOPHOTOGRAMMETRY). Digital recording is done through a variety of techniques, which are currently based on Adobe Photoshop, Auto CAD, or other site-specific or proprietary digital mapping systems. Glossaries of terms have been developed (Weyer et al. 2015; Schmid 2000) for wall paintings.

Conservation of Stone and Petroglyphs

MARK GITTINS

Università degli Studi della Toscana, Italy

A conservation (see CONSERVATION) treatment should have a preliminary phase, in which an object is studied and its condition and deterioration processes are assessed. These are then used to identify the scope of the treatment—at a minimum, halting or minimizing the deterioration and stabilizing the work—and the possible methods to achieve the desired results.

Characterization and identification

Before undertaking a treatment, it is important to characterize the stone, because treatment methods that can be quite safely applied to one type may damage another; for example, acidic solutions used to clean granites will degrade limestones.

Ideally, characterization (see CHARACTERIZATION OF PETROGLYPHS) will go beyond the simple lithotype identification to include factors such as porosity, pore size and distribution, the presence of other minerals, especially those sensitive to water, and the stone's structure and mechanical strength. These characteristics may be more important to the deterioration and treatment of a stone than its mineral composition. For example, different limestones decay in very different ways, and some tuffs become more subject to water damage after some consolidation treatments.

Once a material has been characterized, a literature search should be carried out to see what treatments have been used in the past.

It is also extremely useful to find other examples of the same stone in situ, in order to observe its behavior in other conditions and

after treatments. Clearly tests should always be carried out before starting treatments.

Description and documentation

Documentation (see CONSERVATION DOCUMENTATION) is a key aspect of any treatment, though it is often underresourced in terms of time, funding, and means. While there is no universal glossary for stone conservation, ICOMOS-ISCS (2008) provides a useful starting point for condition reporting, although it is skewed toward outdoor architectural monuments.

Complete documentation should also include original working techniques (tool marks, joins, fills, etc.), details of applied decoration (paint, gilding), previous interventions (patination, fills, etc.) and full details of the present treatment. Each new phenomenon should be described using the tripartite structure of the ICOMOS glossary: it should have a unique descriptive term, a written, unambiguous definition, and a clear illustrative photograph.

In association with this documentation, environmental monitoring should be carried out, preferably in the long term but at least in the medium term, in order to record factors that could affect the stone's condition.

Treatment planning

The data collected should help determine the causes and the nature of the deterioration, and hence make proposals for treatment. Ideally the treatment should form part of a medium-term to long-term conservation site management plan (Loubser 2001). If the site is a museum or a collection, the plan is likely to be much less complicated than if it is an open-air site with many stakeholders (see CULTURAL RESOURCES MANAGEMENT).

One factor that it is important to clarify between stakeholders at this moment is the desired goal of the intervention: the level of

treatment, what future conditions the work will have to support, and what aesthetical treatment is required, if any.

In general, the first option that should always be considered is no intervention at all, except perhaps monitoring. This is especially important in the case of rock art, and particularly on open-air sites. In those contexts, even small interventions can significantly change site dynamics and radically accelerate deterioration. Hence it is especially important to carry out small-scale tests—ideally, tests monitored over a period of time—prior to any treatment.

Another option is not to intervene directly on the stone but rather to protect it from deterioration by employing preventive conservation (see PREVENTIVE CONSERVATION IN ARCHAEOLOGICAL SITES). However, the previous caveat about treatments with potentially damaging consequences still holds true: in many cases, supposedly protective measures have caused an acceleration in degradation.

Generally current practice prefers *minimal interventions*, though it is not always clear exactly what this means, especially if the final goal of the treatment has not been clarified. It is also worth bearing in mind that, if the stone is in a fragile state, a minimal intervention designed to stabilize it means that after the treatment the stone will probably still be quite fragile and will require a follow-up maintenance program that should guarantee its well-being.

Cleaning

Cleaning may be carried out for many reasons, from aesthetical ones (e.g., removal of accretions obscuring the stone) to conservative ones (e.g., removal of corrosive black crusts from limestones). The desired results should be carefully considered, as cleaning always involves some degree of stress or damage to the underlying stone—or perhaps even the removal of transformed original material.

The level of cleaning is often context- and culture-dependent to a high degree. For petroglyphs, it is essential to maintain the natural patina (rock varnish), which both protects the

stone and contains material by which the petroglyphs can be dated. In Italy, for example, it is generally considered correct practice to keep oxalate patinas on archaeological stone and sometimes to retain, as part of the work's history, the artificial patinas applied during restorations.

There are several broad categories of cleaning, and the systems involved vary from cleaning of large-scale archaeological monuments to precision cleaning of minutely carved objects.

Water cleaning

High-pressure water or steam cleaning is generally not considered suitable for archaeological material. For large surfaces, a more controllable method consists in using compressed air to produce fine water sprays or atomized water, in the form of a fine mist. Cleaning occurs through the heightened solubilizing activity of the water, not through water pressure. However, the systems require constant supervision from trained conservators, to avoid excessive cleaning and release large amounts of water.

Further, many stones are unstable in the presence of water, and larger objects may contain water-sensitive components (metals, wood etc.)

Chemical cleaning with solvents/solutions and poultices/gels

When treatment requires the chemical transformation or solubilization of extraneous materials (gypsum crusts, coatings, calcified surface grime, etc.), chemical agents can be applied in cellulose fiber or clay poultices or in gels thickened with polysaccharides, cellulose ethers, silicon esters, and so on. These reduce the evaporation of the chemicals—and hence toxic vapors—and increase possible contact times. Possible complications are related to the regulation of the cleaning levels, residues and reaction products, the safe disposal of waste, and the difficulty of large-scale work. Materials applied range from organic solvents to detergents and acid, alkaline, or chelating solutions.

Laser cleaning

Sometimes lasers give results unobtainable by other means. They are, however, expensive, fragile for site work, and often slower than other methods; and they may cause damage or staining.

Mechanical cleaning

These methods often provide fine control over the removal of adherent extraneous material, though they can cause damage, especially if the stone is more fragile than the material to be removed. Apart from handheld tools (brushes, scalpels, dental tools, hammer, chisels), there are powered tools such as ultrasound ablaters, pneumatic or electric gravers, microhammers, microdrills, and so on. Often these tools are used (together with chemical or water cleaning) to reduce the thickness of deposited material before microabrasion.

Air abrasion and microabrasion

There has been much development in the field since the beginning of the twenty-first century: the tools available range from small portable instruments to large-scale systems that still maintain fine control levels. Jet diameters range from fractions of a millimeter to centimeters, pressures from tenths of an atmosphere upward, and abrasive materials from carborundum down to plastic and cork powders. Abrasive methods work most effectively and safely on uniform deposits; frequently they are used to finish a surface “regularized” by chemical and/or mechanical methods. An experienced operator can achieve very fine gradations of removal, but incautious use can provoke pitting, scratching, and erosion. The dispersal of the abrasive particles can cause problems, particularly in public spaces.

Variations include mixed water/particle systems and, recently, the use of dry ice abrasive; the latter adds a thermal component to cleaning and eliminates the problem of abrasive powder collection.

Biological cleaning

Research on the use of biological agents for cleaning is going on, and at least one product—based on sulfate-reducing bacteria—has been marketed. Biological agents are highly selective and self-limiting, but for the time being the possible problems are slowness, the small-scale character of treatments, and residues; and they require narrow temperature, pH, and humidity ranges to work.

Removal of biological growth

A key but difficult area. The growth of microorganisms and plants—or their removal—can cause severe damage to stone, but chemical treatment can be problematic: biocides and herbicides are frequently toxic for other lifeforms, they often have undesirable physical/chemical characteristics (surfactants), they may cause staining, some materials (alcohols) may act as nutrients. It is unrealistic to expect stone, especially outdoors, to remain sterile, but no treatment plan should rely solely on regular use of biocides. A preventive approach should be considered.

Recent research has included bioinhibiting coatings for open-air archaeological surfaces, while UV light may be a possible solution when treating unpainted surfaces.

Consolidation and consolidants

Introduction

When analyzing stone condition and selecting appropriate treatments, it is important to distinguish between the need for consolidation and the need for adhesion, though there may be overlap. However, a material that is good at consolidation is frequently a poor adhesive, and vice versa.

Consolidation is required when a stone is weakened at the microscopic level or powdering. An ideal consolidant will be physically and chemically compatible, will penetrate a substrate, will remain *inside* while curing, and will leave the stone still porous, so that it can be *treated again* if necessary.

The effectiveness of a consolidant depends greatly on a stone's porosity, strength, and composition. These parameters vary greatly between lithotypes; and consolidants vary considerably in their efficacy, depending on stone type and the condition at treatment (Wheeler 2005).

Effective consolidation also means that the consolidant stays inside the stone as it sets or cures. But when the liquid containing the consolidant evaporates, it tends to draw the consolidant to the stone's surface, where it may form a crust; this means that the method of application frequently makes a big difference to whether a consolidation works or not.

Types of consolidants

Numerous materials have been used for the consolidation of stone, and research is very active.

One of the most commonly used consolidants for stone is ethyl silicate or tetraethyl orthosilicate (TEOS), which is widely available commercially in many different varieties: pure, diluted with various solvents, elasticized with hydrophobic additives. In its natural state it is a low-volatility liquid and has better penetration and retention than many consolidant-solvent combinations. Major disadvantages of TEOS are its cost and its long curing time (20–30 days).

There is debate as to its long-term suitability for nonsilicate stone (e.g., limestones, marble), given its lack of chemical affinity with it and possible decay. However, in the short to medium term, TEOS appears to be at least as effective as other materials.

Other inorganic materials used on some lithotypes include nanodispersions of silica in water and nanodispersions of lime in alcohols, though they can have problems with good penetration. There are also ammonium oxalate, ammonium phosphate, and barium hydroxide.

Many organic materials, especially synthetic resins in solutions or dispersions, have also been used, though often these are better suited as adhesives, owing to their poor penetration and film-forming characteristics. However, good results have been obtained for smaller-particle acrylic microdispersions, though there is discussion about their long-term stability.

Adhesives and joining materials

It is frequently necessary to join separate pieces of stone. These may be separated fragments, distinct parts originally fixed together, or later additions applied for aesthetical, protective, or functional reasons.

An effective adhesive should have good penetration *between* pieces of substrate but poor penetration *inside* the substrate. Traditional adhesives included natural resins, cements, and molten lead, often combined with metal pins or cramps, while in more recent times synthetic resins such as epoxies or polyesters have been used.

These methods have been refined to aid reversibility and reduce damage from metal corrosion—it is now good practice to use soluble resin barrier coatings prior to applying adhesives, to employ corrosion resistant (stainless steel, titanium, carbon fiber, fiberglass) pins, and, where possible, to tailor treatments more strictly to needs: to eliminate pins where possible and to employ more reversible adhesives.

To reduce the invasiveness of these treatments still further, there is experimentation with screw-held, spring-loaded, or sliding pins, rare-earth magnets instead of adhesives, and external or internal frameworks designed to hold the parts together. Due to the greater complexity of these systems, they tend to be employed in museums or indoors (Podany 2009).

When there are cracks or fissures in stone, but not full separation, possible treatments include injecting an adhesive or a grouting mortar. Prior to treatment the crack must be sealed, to prevent outflow of the injected material. However, it is difficult to control the process and to verify the result.

Fills, coatings, and protection

Once a work in stone has been stabilized and cleaned, it is frequently good practice to fill cracks and at least some voids, particularly if the object is exposed to further deterioration processes: losses frequently allow the penetration of water

or extraneous materials, causing further deterioration or allowing plants or microorganisms to colonize.

The filling material should be stable and physically and chemically compatible with the substrate and have an acceptable appearance. Often this involves mixing stone powder and/or pigments with a suitable binder, though the choice of binder will depend on the stone type, the desired appearance, and whether it is used indoors or outdoors. Binders for carbonate stones are usually lime-based, and those for sandstones are silicate-based. Synthetic resins or waxes have been used for highly finished, transparent, or reflective surfaces, though there may be problems of removal, color change, and stability in general.

If the stone is fragile and is subject to wind or water erosion, it is often useful (albeit a short-term expedient) to employ plaster shelter coatings: a thin layer of fine mortar is pressed onto the stone, so that it acts as a sacrificial layer against a source of erosion. This technique is most commonly used for limestones or marbles, as is the more recent (and related) use of oxalate or phosphate solutions to consolidate the stone and form a permeable but resistant calcium oxalate or phosphate coating for surface consolidation or protection. Bacteria have also been used to create a biocalcified protective layer.

Another frequently used protection is water-repellent coatings, especially for outdoor stonework. The most common materials are silicon and fluorinated polymers, although there is some debate as to how long they last, especially on the various stone types. In many cases similar coatings, or even microcrystalline waxes, are applied to indoor stone to protect it against airborne deposit or people who touch the stone.

Unfortunately there is an increasing call for anti-graffiti coatings on cultural property, though these need to be evaluated carefully prior to use: they are often similar to water-repellent coatings but tend to be less permeable and possibly more difficult to remove.

Once again, it is very important to weigh up whether the application of treatment products, even fillings, and especially protective coatings, is desirable and will not lead to destabilization or the disruption of a current equilibrium and to

further problems, especially in the case of Rock art and petroglyphs.

Aesthetical treatment

The question of the final aesthetical treatment can be extremely complicated, since it brings together a wide range of cultural, art-historical, and methodological factors, and aesthetical approaches can range from completely hands-off reconstruction to full-scale reconstruction. This is not the place to consider the multiple ramifications of the issue, so the discussion will be limited to a few more standard methods employed in some of these treatments.

The question of fills was briefly discussed above. For finding a fill material that imitates or resembles a worn stone, usually an inorganic binder is used (lime mortar or silica dispersion, or even TEOS) with powdered stone and/or pigments. In some cases the fills are laid at a slightly lower level than the surrounding stone, deliberately “declaring” the loss, or are left with a surface finish or color that distinguishes them from the original stone. Imitative fills—especially of moderately or highly finished stone, or of semitransparent stone—are difficult to achieve with these binders and, as mentioned above, pigmented synthetic resin or wax binders have often been used.

Sometimes parts are reconstructed. They can be made by using filling materials, synthetic resins casts, or even 3D printers; but sometimes they are made from stone. When stone is used, sometimes the material is chosen to be as similar as possible to the original, but generally some characteristic is used to *indicate* the substitution: the stone may be of a different color or type, or the surface may be finished in some distinctive way. Other materials are generally tinted to match the original, as there is no danger of confusing them with the original stone.

Finally, the stone itself—particularly sculptures or decorative works—may be retouched or treated with an artificial patina for situations where the appearance is uneven, or where fills or stone inserts are visually disturbing. Colors are usually applied using nonpermanent binders, for example watercolors for indoors, or pigments

mixed with reversible synthetic resins such as aldehyde resins, or products used for a surface protection. These tints may be transparent or a whitewash—an opaque layer applied to hide stains.

Future maintenance

Once any conservation treatment is completed, the work should be subject to programmed follow-up inspections that monitor its well-being and ensure the continuing validity of the treatment.

FURTHER READINGS

Conservation of Vitreous Materials

STEPHEN P. KOOB and N. ASTRID R. VAN GIFFEN

Corning Museum of Glass, USA

Vitreous materials include glass, high-fired ceramics such as china and porcelain, and any type of ceramic that has a glaze or glassy surface or matrix, such as faience, stonepaste, and frit. Many of these have similar physical natures and properties that are closely related. Only glazes on low-fired ceramics fall into a somewhat different category, as the glazes are similar to glasses but with varying substrates (earthenware or terracotta). Knowing the chemistry and physical properties of silica-rich materials is critical to selecting the materials needed for conservation treatment. Natural resins have been generally abandoned for treatment use as they are not as stable, dependable, or predictable as modern synthetic resins.

The three major *active* conservation interventions are *consolidation*, *adhesion*, and *loss compensation*. *Passive* conservation management involves climate-controlled storage with year-round monitoring. *Consolidation* may be defined as the strengthening of porous and permeable materials using a dilute resin. It can simply be termed “adhesion in three-dimension.” The primary reasons for consolidation include stabilization, prevention of additional deterioration, or strengthening of an object for handling. *Adhesion* of fragments, or assembly, is one of the most common purposes of conservation treatment, as separate fragments may not be presentable or intelligible. *Loss compensation* is a *restoration* technique that is often carried out in order to provide additional structural support or for aesthetic enhancement for museum display. This is a complicated subject, too detailed to be covered here.

The eventual disposition of an object, or groups of objects, should certainly be considered before

any intervention is carried out, whether the object is to be housed in storage, studied, published, or placed on display.

Consolidation

China, porcelain, and glass

China, porcelain, and glass are virtually nonporous and nonpermeable, have minimal porosity (<1%), and therefore do not require consolidation. However, their deteriorated or weathered surfaces may require consolidation; this is especially true of archaeological vitreous materials that have fragile, friable, or lifting weathering layers. Even in these cases, the glass itself and the high-fired ceramic bodies of china and porcelain remain nonporous, and an application of a consolidant on the undeteriorated areas is not necessary as it would simply coat the surface.

Faience, stonepaste, and frits

Faience, stonepaste, and frits are vitreous materials that have a silica-rich matrix, with a glaze or glassy surface. The surfaces can be compromised much as with the group above, but the body or matrix can also suffer as it is more porous and permeable. The deterioration can manifest itself in many ways, from breakdown of the silica matrix, resulting in breakage, or a weak structural stability. This can be caused by an aggressive burial environment or contamination with soluble salts. Consolidation may be required for both the surface and the underlying silicate matrix or body.

Treatment

The most common consolidants are synthetic resins applied in dilute form. Solvent-based resins are very effective, but in some cases, a water-based acrylic colloidal dispersion may be a suitable choice.

Prior to consolidation, deteriorated surfaces should be examined carefully and properly

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0125

documented (written documentation and/or photography) and permission must be received to carry out the intervention. This may seem irrelevant, but considerable information has been lost by the omission of these steps. Furthermore, if the object is an important artifact from an archaeological or anthropological site, information and samples may be required for dietary analysis, wear, use, dating, or provenance. Consolidation may interfere with these analyses and therefore should not proceed until these questions are resolved, or samples are taken for analysis.

Choice of consolidant

Ideally, a consolidant should be dilute enough to penetrate and strengthen the weakened or loose surface or silicate substrate. For solution resin polymers, this translates into a solids:solvent ratio with a low viscosity. A resin concentration too low will penetrate well, but may impart little or no strength, while one too high may provide more strength, but will not penetrate deeply. Poor penetration can result in a “surface” consolidation, which is no better than a coating. Solvent resins, by their very nature, penetrate better than water-based emulsions or dispersions, but require more care and higher safety measures. Water-based consolidants may be useful especially when very large areas need to be consolidated and the use of solvents is almost impossible.

Although numerous solvent resins are available, and many have been used for consolidation, *Paraloid B-72* stands out as the best choice. It is a stable acrylic copolymer, reversible, and non-yellowing, and has known solubility. It has a very low viscosity in solution, particularly at low concentrations (5–15%). It has a moderately high glass transition temperature (T_g) (40 °C) and can be used safely in nontoxic solvents. It has very good strength and yet is permeable to water, if the consolidation is used as a pretreatment to desalination.

Solvent choice is important, not only for the resin penetrability, but also as a health and safety concern. Early consolidation recommendations often suggested a very slowly evaporating solvent such as toluene or xylene, but these should not be

used for two reasons: These solvents are highly toxic, and solutions have a significantly higher viscosity (Rohm and Haas 1983). Solutions in acetone or in acetone:ethanol are preferable, as they are less toxic and penetrate better. For example, *Paraloid B-72* in acetone (5%) is half as viscous as *Paraloid B-72* in toluene (5%), meaning the consolidant should penetrate twice as deeply. In reality, other factors may influence the penetration of the consolidant, including the application method, ambient temperature, and humidity. The various application methods include brushing, spraying, immersion, and capillary draw (see below).

The consolidant solution should be prepared to achieve the desired result. In some cases, weathered layers are so thin and fragile that touching the surface causes loss, and even a light wind or uncontrolled breath can cause the layers to lift and fly away. A very low concentration (<3% w/v) may impart little or no strength, while a high concentration (>15%) may not penetrate at all. Often a 4–5 percent solution is ideal, but instances of open gaps and lifting surfaces may require a 15–20 percent solution (or a thicker water-based colloidal dispersion such as *Primal WS-24*). This needs to be assessed for each class or group of objects being treated and simple testing with a few different solutions often answers the question. Several different concentrations (5%, 7.5%, 10%, and 15% w/v) should be prepared, and if kept sealed, can be used and reused. *Paraloid B-72* solutions can be quickly made by weighing the resin, placing it in cheesecloth tied with cotton string, and suspending the cheesecloth/*B-72* in a jar of acetone (measured out to the correct amount). No agitation is required; even 150 g will be dissolved in 1 liter of acetone in one to two hours.

For warm or hot climates, a small amount of ethanol can be added (e.g., 90% acetone:10% ethanol). High quantities of ethanol are not recommended because ethanol is extremely hygroscopic and attracts water to itself and can compromise the *Paraloid B-72* solution.

Another acrylic that has proven useful for the consolidation of large loose or friable surfaces is the colloidal dispersion *Primal WS-24*. It is supplied in water and visually appears similar to the acrylic emulsions, but has several different properties (Koob 1981). The very small particle

size and charged particles keep the dispersion from settling out, and the viscosity is much lower than acrylic emulsions (but much higher than solvent resins). One additional benefit is the neutral pH (7.0), whereas acrylic emulsions are higher (pH 8–10). The strength of the acrylic resin is similar to Paraloid B-72 and it has a similar Tg (40 °C). The white dispersion dries clear and is readily soluble in acetone. Primal WS-24 concentrations are made simply by diluting the supplied Primal WS-24 with deionized water. Because it has a higher viscosity, dilutions should be in the range of 10:1 (water:WS-24) to ensure maximum penetration.

Without question, the water-based Primal WS-24 does not penetrate as well as Paraloid B-72 in solution, but its advantages include the lack of solvents (no health hazard), appropriateness for large applications, and lower associated costs.

Applications

The consolidant is generally introduced or applied by brush or pipette. Spraying and immersion are not recommended, as these techniques may cause the weathering or loose surfaces to be dislodged or lost. It is often sufficient to introduce a small amount of consolidant along the edges and allow it to be drawn in by capillary action. In this manner, the consolidant gently finds its own way through the open and permeable layers, strengthening and binding the layers as it dries. Entire consolidation is not recommended as this “seals” and coats the surface of the china, porcelain, or glass and may trap moisture underneath. This can potentially lead to other stabilization problems.

A consolidated surface may be very weak until the consolidant has fully set and all the solvent has evaporated. For both Paraloid B-72 and Primal WS-24, excess consolidant can be cleaned-up easily using acetone and a soft brush, constantly rinsing the brush in fresh acetone. Cotton swabs or toweling are not recommended as they may disturb the surface and leave cotton fibers attached to the B-72.

Work conditions may need to be modified for extreme environmental conditions. Outdoor, on-site archaeological conservation should

be avoided unless the working area is shaded. Indoor and shaded areas will be cooler and more comfortable than working in the sun, and more stable and better controlled for applying consolidants.

Reversing a consolidation treatment is not always practical as the consolidated area might swell and dislodge.

Adhesion

Adhesives are primarily used to assemble broken fragments of vitreous materials. Numerous adhesives have been recommended, but few provide consistent results. Some guidelines for selecting adhesives are: the adhesive should not damage the object, during either application, curing, or aging; it should bond well; it should be removable or “reversible” without damage; be “water” clear; remain stable; and be easy to use with consistent results (Koob 2006).

Two completely different adhesives are recommended for the repair of vitreous materials: Paraloid B-72 and epoxy resin adhesives. Although there are many others, these have become the most popular and familiar. Paraloid B-72 adhesive (discussed above for consolidation) is made up as a thicker resin:solvent solution and sets by loss of solvent. It has a moderate strength, which is especially suited for earthenwares and terracottas, but can also be used on stoneware, porcelain, china, and glass, as well as faience, stonepaste, and frit (Koob 1999). Epoxy resin adhesives are more complex thermosetting resins. They are two-part systems consisting of a “resin” and a “hardener” and when mixed cross-link over time to a solid, insoluble polymer. There are several very good-quality “conservation-grade” epoxy resin adhesives (Table 1) whose working properties, setting times, and stabilities vary (Koob 2006).

Paraloid B-72 and epoxy resins have advantages and disadvantages. They behave very differently and require significant experience to master. The advantages of Paraloid B-72 adhesive include the above-mentioned stability, reversibility, fast setting time, and low cost. In addition, Paraloid B-72 is a thermoplastic resin,

Table 1 Epoxy resin adhesives commonly used in conservation.

<i>Epoxy</i>	<i>Refractive index</i>	<i>Viscosity (cps)</i>	<i>Working time (hours)</i>	<i>Setting time (hours)</i>	<i>Stability (years)</i>
Hxtal NYL-1	1.52	200–300	8–12	48–96	≤100
Epo-Tek 301	1.539	100–200	2–4	4–8	≤50
Epo-Tek 301-2	1.564	300–600	6–8	16–24	≤100
Fynebond	1.551	Moderately low	8–10	24–35	≤50
Araldite 2020	1.553	130	6–10	16	≤50

so joins can be easily moved, after setting, using a hair dryer. The only notable drawback of B-72, specifically on glass, is the fine air bubbles that develop within the join as a result of solvent loss. For this reason, the epoxy resins are preferred for clear glasses.

Epoxy resin adhesive disadvantages include the potential to yellow, particularly when exposed to high light levels (Down 1986), extremely high strength, very long setting times, short shelf-life, and cost. The extremely high strength can compromise the glass, china, or porcelain; if it is bumped or dropped, the adhesive will not fail and the object will break somewhere else. Epoxy resin adhesives are also virtually insoluble when cured and very difficult to remove.

Preparing Paraloid B-72 and epoxy resins for use as an adhesive

It is highly recommended that Paraloid B-72 solutions be made fresh by conservators, especially for ceramics and glass. Koob details the preparation and use of Paraloid B-72 adhesive for both ceramics and glass, including detailed recipes and step-by-step instructions (Koob 2006; 2009).

In general, epoxy resin adhesives do not require any special preparation, but precise weighing and mixing are very important. They are supplied in two parts and one should always read the manufacturer's recommendations for use, the *Materials Safety Data Sheets*, and the specifications for shelf-life and storage. Epoxy resins are slightly toxic during handling, so gloves should be worn when mixing. Cured epoxy resins are not deleterious to health (Skeist 1977, 327).

Application of Paraloid B-72 and epoxy resin adhesives

Careful planning is required before any repair or assembly is undertaken, no matter what the adhesive. All fragments should be clean, dry, and arranged in a logical order for assembly. This is particularly important for epoxy resin adhesive joins, as they cannot be moved once the epoxy has cured. It is generally suggested that a "dry-run" be carried out to see in what order pieces should be joined. This is generally done with clear tape or masking tape.

Techniques of assembly

Paraloid B-72 Once the order of assembly is determined, the tape is carefully removed and the fragments are arranged in the order that they will be joined. Porous substrates or bodies should be primed or sealed before the Paraloid B-72 adhesive is applied, but nonporous china, porcelain, and glass do not require this step. *Priming* creates a nonporous, nonpermeable "seal" that allows the adhesive to make a better bond or join to the surface. It provides a more compatible surface to bond to, allows for more even application and film formation, and slows down the evaporation and setting of the adhesive.

Priming can be done using a dilute solution of Paraloid B-72 in acetone (5–10%). It is similar to consolidation, so if broken fragments have already been consolidated, they do not require being primed. The adhesive is then applied along one edge of the fragment to be joined and a "piece-by-piece" assembly is carried out, checking all joins as the

assembly progresses. Depending on the size and weight of the fragments being assembled, joins may be held, taped, or positioned until the adhesive has set. The time required for the Paraloid B-72 to set varies considerably (minutes, hours) with the size and thickness of the fragments being assembled and ambient temperature. A binocular microscope is a valuable tool in examining the joins to ensure they are correct.

A more advanced technique that works well with very thin china, porcelain, and glass is to completely assemble all the fragments with tape or small clamps across the joins and introduce the Paraloid B-72 along the cracks. This requires thinning the adhesive (25–30%) but can be very effective. It is commonly used for epoxy resin applications (see below).

Epoxy resins Epoxy resin adhesives are generally not recommended for porous and permeable vitreous ceramics such as faience, stonepaste, frits, and soft earthenware and terracotta glazed materials, since the epoxy resin soaks into these porous fabrics and causes irreversible darkening and staining. They are best suited for high-fired ceramics and glass. Epoxy resins are very different than solvent resin adhesives and they can result in beautiful repairs. Epoxies can also be selected to match a specific refractive index of glass, but require absolute care and attention in their preparation and use.

Epoxy resins can be applied using similar methods as Paraloid B-72 (above), either by piece-by-piece direct application or by capillary draw after taping all the pieces together (generally preferred). Epoxy resins have also been successfully used to stabilize cracks in high-fired vitreous materials. For capillary draw or “wicking-in” to cracks the epoxy adhesive should be used within the first hour of mixing, when its viscosity is lowest. Excess epoxy resin should be cleaned-off the surface of a material as soon as possible after application; otherwise, very strong solvents or mechanical removal may be necessary which poses a risk of damaging the surface. Uncured epoxy resin adhesive can be easily cleaned-off using acetone or ethanol.

Work environment for adhesive use

The difficulty of working in hot climates has been mentioned, but it should also be noted that neither Paraloid B-72 nor any epoxy resin adhesives will provide consistent and dependable results if the humidity is unduly high. If the humidity exceeds 60 percent, it is difficult to work with any adhesive.

Passive conservation

Passive conservation management approaches involve climate-controlled storage with year-round monitoring. Proper packing, housing, shelving, and cabinetry are all important in maintaining a safe and stable storage environment. Open storage with air movement is recommended for most vitreous materials, but this is not always practical for fragments. This subject has been researched extensively and is far beyond the scope of this *Encyclopedia* entry.

Conservation of Waterlogged Materials

EMILY WILLIAMS

The Colonial Williamsburg Foundation, USA

Organic materials are among the most perishable materials archaeologically. They have been used for centuries to create tools, weapons, conveyances, utensils, shelter, clothing, leisure activities, storage containers, and even intricately decorated works of art and ritual objects, but their ubiquity is not always reflected in the archaeological record. However, in certain environmental conditions, such as anaerobic ones, these materials can survive remarkably well. Anaerobic (or anoxic) conditions occur most commonly when air is excluded from the burial matrix as a result of water saturation. Without oxygen, microorganisms that might otherwise consume the organics cannot thrive. Anaerobic conditions may occur in marine environments, but they are most common in the sediments at the bottom of lakes and rivers, in wetland areas such as peat bogs and marshes, and in urban environments where centuries of discarded materials contribute to a raised water table. Locally they can also occur inside well shafts and privies on otherwise dry sites.

When excavated, anaerobic sites rarely yield only one or two artifacts but instead give up large quantities of material. Often the volume of the material found poses tremendous logistical challenges. For example, excavations carried out between 2005 and 2013 at the Theodosian Harbor in Istanbul revealed over 35 ships, ranging in date from the seventh to the tenth century AD (Koçabaş, Özsaıt-Koçabaş, and Kiliç 2012). Similarly, the recovery of the *Vasa* in 1961 produced not only the 600 cubic meters of oak that comprised the ship itself, but also over 40,000 artifacts, many of which were also comprised of organic material. In addition to the logistical challenges posed by the size and volume of many of the finds, there are also time constraints that may

impact their treatment. Once organic materials are removed from their burial environment and oxygen is reintroduced, they become susceptible to renewed microbial attack. Additionally, there is the risk of uncontrolled drying, which can result in severe shrinkage, deformation, and cracking. Systems for keeping organics wet (such as water tanks or sprays), supports for heavier materials, a knowledge of the materials involved, and, above all, a preservation plan are all necessary components for the successful retrieval and conservation of waterlogged organic materials.

Wood

The individual ways in which waterlogged organics deteriorate in the burial environment and the sort of intervention that is necessary after excavation are dependent on both the structure and the chemical makeup of the material. For example, waterlogged wood can appear to be very robust and well preserved when it is initially excavated. Tool marks are often visible and may contain sufficient detail to make it possible to identify not only the types of tool used, but even the use of the same tool on multiple pieces of wood within the same or neighboring structures—which facilitates the study of working patterns (Historic England 2010: 21). However, the surface appearance of wood is frequently deceiving. Structurally, wood is composed of a number of cells made up of three major components: cellulose (45–50%), hemicellulose (15–35%), and lignin (20–35%). Prolonged exposure to anaerobic conditions can lead to the hydrolysis of the cellulose and hemicellulose in the cell. As these are lost, what is left behind is a lignin skeleton filled with water. This skeleton has structure, but little strength. The water inside the cells is providing structural support by swelling the cell walls and filling the cavities (lumina) in the cells. If the water is allowed to evaporate, the cells, too weak to withstand capillary forces, will collapse. Cellular collapse is an irreversible process that has macroscopic results such as cracking, warping, splitting, and

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0126

delamination. In order to avoid cellular collapse, a bulking agent must be introduced before drying.

Since as early as the nineteenth century, archaeologists and conservators have experimented with a number of materials as bulking agents. Alum (hydrated potassium aluminum sulfate) was used extensively in Scandinavia from 1850 to the 1950s. The idea was that the alum, a water-soluble material, could penetrate the wood and reinforce the structure through the formation of alum crystals inside the wood. Important Viking-era finds, such as the Oseberg ship in Norway and the Hjortspring boat in Denmark, were treated with this method. Unfortunately, as is now understood, the alum did not penetrate as deeply as was thought. Additionally, physical damage occurred as the alum crystallized; and, because alum is hygroscopic, damage continues to occur when there are fluctuations in humidity within the storage or display environment. Additionally, sulfuric acid was produced during the application, and it continues to damage the wood. As a result, the method has been abandoned, and mitigating its effects remains a focus of international research. Another historic treatment that is rarely used is the acetone–rosin method. This method was more promising, but the health and safety implications of working with large quantities of heated acetone forced most practitioners to abandon it.

Today a number of chemicals are in use for the treatment of waterlogged wood. They can be divided into two categories: reversible and irreversible compounds. Reversibility, although rarely fully achievable, is an important concept for conservators, since it recognizes the fact that, despite our best efforts, objects will require future retreatment; and it aims not only to facilitate that, but also to ensure that any additions made to artifacts can be removed with minimal impact to the original material. Polyethylene glycol (PEG) is perhaps the most widely used compound for treating wood reversibly. It is a water-soluble polymer that can be applied in a number of ways; timbers may be sprayed with it or immersed in it. Different molecular weights of PEG may be used, depending on the species and degradation of the wood; however, research focused on the behavior of PEG during freeze-drying has suggested that low molecular weight PEG may not freeze, and this may cause future problems. Like wood, polyethylene glycol is hygroscopic,

which means that it absorbs and desorbs moisture from the environment. This can mean that, in environments where the relative humidity (Rh) fluctuates, polyethylene glycol may become sticky and may trap dust or promote mold growth. It may also serve as a transport mechanism for impurities and salts in the wood.

In some countries PEG is expensive or difficult to acquire. Sugars (such as sucrose) have been used as alternatives to PEG. Like PEG, they are water-soluble and can theoretically be reversed as needed. Successful results have been reported; however, fermentation of the sugar solution has also been reported (Hoffmann 2009), and there are concerns about whether the sugar in the wood may attract insects when the objects are in storage or on display. Recently, research into sugars has focused on the potential of sugar alcohols such as lactitol (Hoffmann 2013, 93) and of nonreducing sugars such as trehalose (Imazu et al. 2016).

Irreversible treatments, employed for the preservation of waterlogged wood, include the *in situ* polymerization of monomers using gamma radiation, the use of Kauramin, a melamine resin (Hoffmann 2013, 97–104), and the use of silicone oils (Tejedor 2012). These treatments tend to be significantly shorter than PEG or sugar treatments and the results reported are often very good; but it is important to note that, when wood is treated with these materials, the compounds irrevocably cross-link with the wood, complicating future treatments. One of the advantages of these materials is that they appear to make the wood less susceptible to changes in Rh after treatment.

The efficiency of wood treatments may be measured by both quantitative and qualitative criteria. Quantitative criteria include water content, density, weight change, and measurement of dimensional shrinkage. Qualitative measurements include visual criteria such as color, presence or absence of cracks, changes in surface morphology, but may also include treatment time, cost, reliability, and the personnel and skill levels required for a successful treatment. Due to differences in wood type, preservation, and treatment methods, it can be difficult to reliably compare results from one site or object to another. Documentation techniques, such as 3D scanning, laser scanning, X-radiography, photography, and drawing, are important for recording

condition both before and after treatment and for facilitating long-term comparisons. The chemical characterization of the wood's condition, which uses Fourier-transform infrared spectroscopy (FTIR), nuclear magnetic resonance (NMR), and X-ray diffraction (XRD), is increasingly being employed to report the ratios of lignin, cellulose, and hemicellulose in the wood, as well as the presence of iron and sulfur.

Since the late 1990s, research has focused heavily on the role of acid formation in the deterioration of treated wood. When wood is buried in anaerobic environments, it may accumulate sulfur compounds that may be oxidized after treatment; this results in the formation of acids, including sulfuric acid, which can further degrade the wood. The presence of iron compounds in the wood appears to catalyze these oxidative degradation processes. These processes are often initiated by periods of high Rh, which suggests that it is important not only to attempt to remove iron and sulfur compounds during treatment but also to maintain a stable environment after treatment, when wooden artifacts are in storage or on display. Recent work in waterlogged wood conservation has also focused on the development of new, bioinspired consolidates that are based on materials such as cellulose acetate and chitosan. Although some promising experimental results have been reported, significant work is still needed before they can be used to treat actual objects.

Nonwood organics

Leather is a durable and flexible material that is made by tanning animal skin. Vegetable tans were most commonly used in the past, although since the end of the nineteenth century chrome tanning has been the most common form of tanning. In addition to the tanning agent, dyes may be introduced to color the leather, and oils may be applied to make it more water-resistant. Leather survives well in wet anaerobic environments, especially those where the pH is mildly acidic. Some leaching of the tannins may result from prolonged exposure to waterlogged environments. On terrestrial sites, leather may become discolored and blackened from humic

materials in the burial environment and from the reaction of ferrous irons with tannins, and this may result in the hardening of the leather after treatment. Iron concretions and marine encrustations may also obscure the surface of the leather. Delamination or splitting into two discrete layers may also occur. Although this has sometimes been attributed to issues with the original tanning, it may be more reflective of areas of discontinuity in the collagen fibers. If leather is allowed to dry naturally from the wet state, the collagen fibers that compose it cross-link, causing embrittlement and shrinkage. Treatments have therefore focused on introducing lubricants before drying.

Historically, leather treatments were often drawn from the leather industry and materials such as lanolin, oils, and leather dressings were applied to help soften the surface and lubricate the collagen fibers. These treatments often had to be periodically refreshed, and the overoiling of the leather through time may have led to additional damage. Today polyethylene glycol 400 is most frequently used to pretreat leather and is followed by either controlled air-drying or freeze-drying.

Freeze-drying is a technique by which water is removed from an object through sublimation. It requires specialized equipment, but the advantage is that the technique eliminates surface tension and is therefore gentler on the object, posing fewer risks to cellular and/or fiber structures than rapid air-drying. Freeze-drying may be used for a range of waterlogged materials, including wood, although the size of the freeze-dryer may impose limitations on the size and amount of material that can be successfully treated.

Woven materials such as textiles or basketry may be found in archaeological contexts. These are most frequently composed of cellulose-based plant fibers (such as flax, hemp, or cotton) or protein-based animal fibers (such as silk or wool). The diversity of these materials, coupled with the fact that they are not found as frequently or in the same quantities as wood and leather, explains why less has been published on their conservation. Preservation varies according to the method of construction and the environmental conditions. For example, protein-based fibers tend to survive best in acidic conditions, whereas cellulosic materials survive best in alkaline

environments. Furthermore, woven materials may incorporate a variety of other materials, such as dyes, mordants, metals, and surface impregnants, which may all influence the preservation of the material. Pre-deposition use, such as wear, also impacts postexcavation preservation. As the items deteriorate, dissolution becomes a real risk, as does the potential for breakage and tear. Support (on netting or sieves) is frequently necessary in order to handle the material; and, when removing surface dirt, care must be taken to ensure that fibers do not become abraded or folded. The flexibility of textiles may be improved by the use of a humectant such as low molecular weight polyethylene glycol in the wash water, but cordage and basketry require higher degrees of consolidation and bulking.

Although not strictly organic materials in view of their high inorganic mineral composition, skeletal materials such as bone, antler, and ivory do have significant collagen components. The loss of the inorganic component through chemical dissolution in acidic environments is the greatest threat to these materials, but the collagen may also be lost in an alkaline environment. For robust materials, controlled air-drying may be sufficient; however, in cases where the bone is more fragile, it may be necessary to add a consolidant. The treatment of skeletal materials is complicated by the fact that DNA studies, stable isotope studies, and other analytical techniques may be compromised by the addition of any modern chemicals. It is therefore important to clearly understand and communicate with conservators and researchers about any planned analysis before conservation. In the case of wet human bone, additional considerations may regard the local legislation and the rights of descendant populations.

Although wood, leather, bone, and woven materials are the most commonly encountered waterlogged organics, exotic materials such as coconut shells, tortoiseshell, horn, baleen, apples, and hazelnuts have also been encountered. The International Council of Museums, Committee for Conservation (ICOM-CC) Wet Organic Archaeological Materials working group is an international organization dedicated to the protection, recovery, characterization, and treatment of waterlogged organics. It has built a corpus of publications based on materials presented at its

triennial meetings that provide a good entrée into the treatment of waterlogged organics.

Due to the rapid pace of development, the large quantities of waterlogged organics that can be found at a single site, and the costs in terms of equipment, personnel, and treatment materials, it is becoming more accepted that not everything can be treated. Increasingly, reburial, either in situ or at a surrogate site with a similar burial environment, is being explored as a means of preserving waterlogged organics. Large-scale research projects—such as the Reburial and Analyses of Archaeological Remains (RAAR) project in Marstrand Sweden (Bergstrand et al. 2004)—have set out to study the effects of reburial on archaeological collections and on modern sacrificial samples over prolonged periods. Other multidisciplinary projects, for example the Survey Assess Stabilize Monitor and Preserve (SASMAP) project, have taken a holistic approach to the identification, assessment, and management of marine archaeology sites, developing new techniques for characterization as well as a better understanding of the marine burial environment and of how it is affected by climate change (Gregory 2016). Monitoring reburial projects at terrestrial sites such as Starr Carr and the Rose Theater points to the complex relationship not only between the reburied objects and their environment, but also between the site and its surrounding localities. Land-use changes several miles away can significantly impact the environment on the site and may pose risks for the reburied artifacts. These projects have complemented the development of treatment protocols by generating new information about burial environments and new techniques for characterizing organic artifacts.

Conservation Science

ALISON MURRAY and
AMANDINA ANASTASSIADES
Queen's University, Canada

Conservation science preserves, cares for, and extends the understanding of artistic and heritage objects, along with allied areas of study such as conservation (see CONSERVATION) and archaeology (see ARCHAEOLOGY). Conservation scientists analyze objects in order to identify materials and the extent of deterioration (see DETERIORATION), develop new conservation treatment methods (see CONSERVATION), test materials used in treatments, and determine best practices for object exhibition, storage, and transportation. Conservation scientists have expertise in certain areas, depending on the collection or specific mandate of their museum, gallery, or institution. They may examine paintings, works of art on paper, photographs, archaeological materials, and objects made of glass, ceramics, stone, metals, wood, leather, bone, ivory, textiles, and plastics. The field is therefore applied and interdisciplinary, incorporating aspects of chemistry (whether analytical, organic, inorganic, or polymer science), materials science, engineering, and biology. "Heritage science" is a more recent term that covers conservation science, archaeological science, and technical studies (such as technical art history); also, greater emphasis is being placed on the impact that heritage science has on the economy and on society (Heritage and Golfomitsou 2015).

The beginnings of modern conservation science date back to the nineteenth and early twentieth centuries. The work carried out by founding figures like the German scientist Friedrich Rathgen at the Royal Museums of Berlin, the English scientist Harold Plenderleith at the British Museum, and the American scientist Rutherford John Gettens at the Fogg Art Museum at Harvard set the path of scientific inquiry for examining the manufacturing, deterioration, and preservation of artistic works and archaeological materials (Oddy 2011; Bewer 2010).

The field has grown considerably in the last century and a half. Today conservation scientists may be generalists, concerned with a whole area, such as preventive conservation, or specialists, for example in particular analytic techniques. Still other scientists develop conservation treatment methods with conservators. In order to ensure ethical practice, professional codes and guidelines have been drawn up (see ETHICS IN CONSERVATION) which conservation scientists should follow.

Conservation scientists come to the field by various paths, but most of them begin with an undergraduate degree in some science or engineering field, usually followed by a graduate degree. The opportunity to work on a conservation science topic may come during PhD work or during a postdoctoral or other fellowship. Some scientists choose to take a master's degree in conservation, which allows them a great understanding of the treatments a conservator performs. Others may go directly to a conservation science position.

Materials characterization

Conservation scientists participate in technical studies with colleagues from related fields, in order to gather information about the materials and construction of heritage objects such as wall paintings (see CONSERVATION OF POLYCHROME NATURAL AND ARCHITECTURAL SURFACES), metal objects (see CHARACTERIZATION OF METALS AND ALLOYS; CONSERVATION OF METALS; DETERIORATION OF METALS; and METALLOGRAPHY), and ceramics.

In the multivolume *Artists' Pigments: A Handbook of Their History and Characteristics*, conservation scientists have contributed chapters on specific pigments (see CHARACTERIZATION OF PIGMENTS) that are of use to conservators and other professionals. For example, Kate Helwig (2007) focuses on natural and synthetic iron oxide pigments, covering the terminology, the pigment's properties (spectral reflectance, hiding

power, permanence, and other chemical and physical properties), its composition (including sources and preparation), its identification and characterization through microscopy, chemical tests, and various analytical techniques, and its use in heritage materials and in various time periods.

Results from the work of conservation scientists may also indicate cultural information such as historic trade routes. In one example, the chemical characterization of amber from 11 different deposit sources in Canada was possible with the help of a number of analytical techniques (Poulin and Helwig 2016). When amber beads from three Thule sites were analyzed and the results were compared with those from the deposit sources, possible tradelinks were identified between a deposit source in Cedar Lake, Alberta, and the Arctic. This example demonstrates the overlap between archaeological science (see *ARCHAEOLOGICAL SCIENCES*) and conservation science, as discussed by Artioli (2010).

Evidence of the presence of anachronistic materials, which are not in keeping with the attributed age of the object, may indicate a forgery, as explained in Paul Craddock's comprehensive guide on determining the authenticity of a wide range of antiquities and artistic creations through technical and scientific study (Craddock 2009).

Deterioration of materials

Conservation science research into materials and the way they degrade, for example by oxidation or hydrolysis, is used to direct conservation and preservation strategies (see *DETERIORATION*). This operation may include setting up an appropriate storage environment to slow down deterioration, perhaps by modifying the relative humidity or temperature.

The extensive body of research carried out by David Scott at the Getty Conservation Institute focuses on characterizing the structure, morphology, and corrosion of ancient and historic metallic materials (see *METALLOGRAPHY*). Members of the European Federation of Corrosion (EFC) also study the corrosion and conservation of metallic artifacts designated as heritage. Such efforts make a significant contribution to our

understanding of the forming and deterioration of metal objects and are a driving force for establishing conservation treatment and long-term preservation protocols (Dillmann et al. 2013).

Mitigating deterioration: conservation treatments

Scientists collaborate with conservators in developing new treatment methods and materials with a scientific basis that can be applied directly to objects (see *CONSERVATION*). Research in this area may address procedures such as cleaning or reduction of soiling, soluble and insoluble salts, and corrosion products; consolidation of weakened and degraded materials; reconstruction of broken elements; and restoration of areas of loss. Case studies of such work can be found throughout conservation and related literature.

Materials used in any treatment must be of conservation grade or archival quality. For example, adhesives in conservation treatments have been rigorously tested for yellowing, solubility, strength, and pH (Down 2015). Such tests often use accelerated aging, whereby, in order to estimate how materials will react over time, samples are exposed to intense environments, for example high relative humidity and temperature, to speed up reactions. This is a method used in other fields but is not an absolute measurement; to be valid, the accelerated degradation pathway has to be the same as the actual degradation pathway.

Mitigating deterioration: environmental conditions and preservation materials

A first step in mitigating deterioration is identifying threats to the heritage material; the Canadian Conservation Institute (CCI) describes these threats in its web resource on agents of deterioration (Canadian Conservation Institute 2016).

Conservation scientists, in collaboration with building professionals and conservators, also work to establish environmental protocols designed to protect collections in exhibitions, in storage, and during transportation. Such work includes developing environmental standards

for display case lighting and guidelines for the relative humidity and temperature ranges appropriate in specific circumstances. It also involves recommending materials, for example for the long-term storage of archaeological objects made of ivory and ceramics, after excavation.

Using only materials designated as “conservation grade” or of archival quality is crucial for the long-term preservation of artistic and heritage objects. Materials in contact with these objects also need to be identified in order for us to ascertain whether they are safe; examples are materials in gloves used to handle collections, materials used for packing and mounting collections, and materials used in storage and display cases. Studies have shown, for instance, that wooden storage furniture commonly used earlier on to house archaeological collections gave off gaseous volatile compounds such as acetic and formic acid, which reacted with metal objects to form new corrosion products.

Analytical techniques and scientific methodology

Analytical techniques are depended upon by conservation scientists; the rapid development of emerging technologies associated with them results in an increasingly diverse and sophisticated instrumentation. It is imperative that researchers working with conservation scientists frame specific questions regarding the chemical and physical properties of the objects being studied, so as to determine the line of scientific investigation that employs the appropriate instrumentation and will obtain the most accurate results.

Many analytical techniques applied to art objects are discussed in separate entries in this encyclopedia. Numerous books serve as references designed to guide their use and give an overview of the extensive range of techniques applied to heritage materials (Artioli 2010; Stuart 2007). Commonly used techniques are polarized light microscopy (see OPTICAL MICROSCOPY); fluorescence microscopy; X-ray fluorescence (XRF; see X-RAY FLUORESCENCE SPECTROMETRY (XRF)); scanning electron microscopy with elemental dispersive spectroscopy (SEM-EDS; see ELECTRON MICROSCOPY IN CONSERVATION);

X-ray diffraction (XRD; see XRD AND MATERIALS ANALYSIS); Fourier transform infrared spectroscopy (FTIR) (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)); and gas chromatography–mass spectroscopy (GC-MS) (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) (see also CHROMATOGRAPHIC TECHNIQUES IN CONSERVATION). The list of techniques grows as testing equipment becomes more portable or improves in capabilities; examples are portable FTIR, portable X-ray fluorescence spectrometry (pXRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)), macro-XRF, and combined techniques like XRF and XRD. The interest in mechanical testing is growing in the field. The conservation scientist needs to focus on the intricacies of the analytical method, any changes or improvements in the technique, the appropriate methods of sampling and preparation, methods for interpreting the data, and their significance in a heritage context. Collaboration is crucial and conservation scientists regularly work with conservators, archaeologists, art historians, and curators to develop new lines of research.

Results must be interpreted taking into account both the instrument used in analysis and the object analyzed. Reference books like *Handheld XRF for Art and Archaeology* (Shugar and Mass 2012) are invaluable, both by giving an understanding of the general results obtained from the instrument and by covering specific groups of objects. Included are chapters on pesticides in ethnographic collections, archaeological sediments, obsidian, Maya ceramics, glass, paintings, and photographs. Organizations such as the Infrared and Raman Users Group (IRUG) and the Users’ Group for Mass Spectrometry and Chromatography (MaSC) ensure that reference spectral data are available for interpretation and provide an opportunity for members to discuss how the techniques can be applied to heritage objects in sample preparation, analysis, data treatment, and interpretation.

Deterioration

VALERIE MAGAR

Instituto Nacional de Antropología e Historia, Mexico

Definitions

Deterioration can be defined as the process by which something becomes impaired in its form, in its fabric, or in its function over time (Figure 1). It is often used as a synonym of degradation, decay, and damage; however, for some authors, deterioration, degradation, and decay are related to the natural evolution of materials over time, while damage is associated with an instantaneous impact, often of anthropogenic nature. The balance in understanding how change affects both the tangible and intangible aspects that uniquely define each heritage site and object will provide fundamental elements to devise means that will allow the removal or mitigation of deterioration.

Although there are no standardized definitions, deterioration is usually considered to be one of the two possible effects of weathering: deterioration and alteration. Generally, weathering can be described as the natural process that results in the transformation of materials over time, through physical, mechanical, and chemical transformations. It encompasses the changes caused by the passage of time, which are shown as visible aging of the objects or materials. Deterioration is generally considered as a negative condition that is detrimental to the integrity of the archaeological site or object through natural or induced phenomena. It is often associated with material loss, and can include changes in the form, composition, or context of the archaeological heritage. Alteration is associated with the natural evolution of materials, and is not always considered as negative. It may involve the addition of elements, an action that usually happens on their surface. Patina is one aspect of alteration.

Examples of deterioration include structural damage of an archaeological element due to soil

movements, and losses of elements, for example fragments of a mural painting or of building materials. Examples of alteration include changes in color in a material, and biofilm growth on the surface of materials.

Alteration and deterioration may affect heritage in qualitative or quantitative processes of change, at different scales. The analyses provided at each of these levels allow understanding of the different variables of deterioration and alteration, which comprise their condition and type (including defining if they are active or inactive), their location and orientation, their extent and severity, and, if possible, their speed or rate. It will also allow the definition of patterns and trends of alteration and deterioration, and search for potential causes, which will enable devising conservation and management solutions.

Classification

Deterioration and alteration may be classified in various ways, following two essentially different approaches: Some divide them by the effects visible on the archaeological heritage (additions or subtractions), while others focus on the possible causes of alteration and decay (human and natural; physical, chemical, and biological; internal and external factors). It is often easier to see the effects, while we can rarely see their causes, as these may be interconnected and complex. However, it is also easier to explain the causes, which can have a series of different effects, and the published literature therefore tends to use this approach. The most important aspect is to use an organized and hierarchical method in order to systematically analyze the object or site (Magar, Pedeli, and Varoli-Piazza 2005; Pedeli 2014).

Figure 2 attempts to show the most important factors affecting archaeological heritage, using the human and natural division, and separating them according to their potential effects, which may be slow and cumulative, or fast and drastic.

Figure 1 (a) Elements of archaeological heritage potentially affected by alteration and deterioration (modified from Matero 2011, 1), (b) and scales for alteration and decay on archaeological heritage.

The impact of these factors on the physical fabric and form of a site or object, and on their function and meaning, which may be associated with intangible aspects, can be assessed through traditional condition surveys, as well as with cultural heritage impact assessments (ICOMOS 2011). The latter have been developed more recently in order to address greater threats to heritage, including much vaster development projects—for example, mining and extractive

projects, and infrastructure developments—or the impact of climate change—for example, increased coastal erosion, or the thawing of permafrost, which will cause the deterioration of countless archaeological heritage objects/sites that are still buried. Both methods allow understanding of site formation, and the evolution and changes at a site or of an object over time, and define alternatives for mitigation, conservation, and management.

Figure 2 Alteration and decay of archaeological heritage divided according to their causes and the rate of their effects.

Source: Modified from ICCROM (in Berducou 2000, 18).

Perception of alteration and deterioration in archaeological heritage

It is widely accepted that the aim of conservation is to protect heritage from loss and damage. However, how an archaeological site or object is experienced and understood may vary from one context to another, based on cultural beliefs associated with it. In the western tradition, where

a time span separates modern viewers from most archaeological heritage, conservation will consider the often ruined state of those archaeological sites or objects as part of their historical evolution; it will be considered as part of its important significance and meaning. In such instances, only a stabilization treatment will be sought, in order to preserve the character and authenticity of such heritage.

In other cultural contexts, however, especially in sites that still have a symbolic or religious meaning, and where cultural continuity exists, a ruined site may signify a lack of respect; such would be the case in the Buddhist tradition, for example, where a complete restoration and reconstruction may be sought, as an act of religious merit (Wijesuriya 2010). In other places, the role of traditional communities in the understanding of declared archaeological sites has been important to define how change at those sites should be perceived (Ndoro 2005).

Another important element in how alteration and deterioration are comprehended involves a time factor—that is, whether the changes created by weathering proceed from a slow and cumulative effect, or if they are the result of events such as war, vandalism, or acts of terrorism. With the latter, the trauma caused by these violent events usually created an entirely different response from local and international communities, triggering responses for conservation treatments that would not necessarily have been considered appropriate in other contexts, particularly with regard to reconstruction.

In essence, alteration and decay are involved with change over time; and the way society understands those changes, and embraces or rejects their effects, will dictate the measures or acceptance, mitigation or creation of new changes through conservation and restoration measures.

Deterioration of Earthen Building Materials

XIAO MA

National Gallery of Art, USA

Earthen buildings require the use of unfired earth. Built as early as 9000 BC (Mileto et al. 2011), earthen buildings appear in both archaeological sites and modern constructions, where their types range from large complexes and historical centers to individual structures and decorated surfaces (Avrami and Guillaud 2008). The types of earthen buildings (adobe, rammed earth, wattle and daub, cob wall, compressed stabilized earth block, etc.) and the construction techniques may vary with people's culture, climate, and resources.

Used as a building material, earth is a mixture of clay, silt, sand, and, occasionally, larger aggregates such as gravel and stones. The geotechnical names of the constituents depend on the diameter of their particles: those with a diameter smaller than 0.002 mm are called clay; those with a diameter between 0.002 and 0.063 mm are called silt; those with a diameter between 0.063 and 2 mm are called sand; and those with a larger diameter are called gravels and stones (Minke 2012).

The forces that keep earthen materials together come from the natural binding forces of clay minerals. Clays are generally made of alumina and silica sheets. Due to their very small size and to their layered arrangement, clay crystals have an extremely large surface area to volume ratio. The binding force originates in the electrostatic charges between the sheet layers of the clay, which are not electrically neutral (they have negative charges). As a consequence, the clay mineral surfaces attract water molecules through the electrostatic forces; and the water molecules penetrate between the layers, causing an increase in the distance and a weakening of the connection between them. This gives the plasticity, cohesion, and volume-change properties of the clay minerals and shapes them into building materials.

When damp, the clay minerals swell and become plastic and cohesive: they deform when an external force is applied, and retain the deformed shape when the force is removed. When dried, they become hard and brittle (Henry et al. 2015).

The earth used in construction normally contains 20–30 percent clay and silt, the remaining amount being sand. This ratio could be found in natural sediments and, if it is not available on the earth near the building site, sand would be mixed with the earth in order to produce a correct mix (Torraca 2009). It is common practice to add earth modifiers or additives during preparation. The modifiers or additives may be inorganic, natural, or synthetic organic materials—for example, fibrous materials (plant and animal fibers), which increase strength and reduce shrinkage cracks; gypsum, lime, cement, asphalts, and bitumen, which are used as soil stabilizers; natural resins, used as adhesives that bond the soil particles together; plant oils and animal fats, which add water repellency to soil and increase hydrophobicity, and so on (Oliver 2008b).

According to the specifics of each construction type, different techniques would be employed to build the earthen structures. For instance, the adobe technique is applied by mixing the earth with water into a liquid state, giving it the desired shape in a mold, then drying the adobe blocks; the rammed earth technique is applied by slightly dampening the earth until it reaches the desired state, then placing it into a mold of the size of the final object, and finally applying a high-energy impact (Velde 2008).

Although earth is one of the most widely used construction materials in the world, it's one of the most vulnerable, too, and earthen materials are susceptible to deterioration. General pathologies of the earthen materials take the form of nonstructural and structural damages. Some common nonstructural damages are delamination/detachment, disaggregation (i.e., loss of binder), flaking (in which thin, small surface layers loosen and flake off), blistering (which looks like bubbles beneath the surface), biological growth (which could be of anything from molds

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0171

to vines and plants), and nonstructural cracking (i.e., cracks that have no effect on the structural integrity of the building; see Cancino and Crosby 2011).

Structural damages include structural cracking (i.e., cracks that affect the integrity of the building and have various shapes—vertical, horizontal, diagonal, X-shaped, etc.), settlement of walls (i.e., the sinking of walls/foundations), lack of physical connections or junctions between the building's components (e.g., between walls), and partial or total collapse.

The factors that can cause the deterioration of earthen building materials may be categorized into three types: environmental factors, human and animal activity, and external factors. These are elaborated upon in what follows.

Environmental factors include wind, excessive moisture, temperature and temperature change with moisture, and vegetation or biological growth.

Wind could cause abrasion and displacement of surface materials in a direct way. It could also accelerate evaporation and deposit deleterious materials on the surface; and, in polluted areas, the sulfur oxide and carbon oxide in the wind could produce carbonic and sulfuric acid with water and thus cause, indirectly, further deterioration of the earthen building materials.

Excessive moisture is a very common factor that causes the deterioration of earthen materials. It can take the form of vapor (through relative humidity or hygroscopicity) or liquid (through condensation into ice, as rain, or as dispersed water and groundwater). The erosive action of rainwater and dispersed water in particular can cause earthen materials to lose their cohesive strength. The subsequent drying of the earthen building roofs, walls, and wall surfaces can further cause the formation of furrows, cracks, deep fissures, and pitting. If left unattended, rainwater can eventually destroy the walls and the roofs, leading to continued deterioration and ultimate collapse. On the other hand, groundwater—possibly coming from a high water table, improper drainage, or seasonal water fluctuations—will rise through capillarity into the wall and the bonding force between the clay particles in the earthen materials will break down, causing the earthen materials to erode, bulge, and cove. The dissolved minerals or salts brought up

by the water can be deposited on or near the surface of the wall as the moisture evaporates, leading to salt efflorescence and deterioration of the earthen fabric. As the earthen materials dry out, shrinkage cracks usually appear and loose sections may crumble (de Teel Patterson and Look 1978).

Temperature and temperature change with moisture could bring on freeze and freeze–thaw cycles. When the temperature drops below 0 °C, ice formation (freezing) would occur (Torraca 2009). When the temperature changes with the moisture in certain conditions, a freeze–thaw cycle may occur, following several steps: (a) saturation of the earthen materials through moisture from precipitations (rain or snow); (b) freezing of the accumulated humidity, causing crystallization and expansion of the water; and (c) thawing of the ice, leading to the presence of water as liquid. This may cause serious damage to frost-susceptible materials (Rainer 2008).

Vegetation or biological growth is a natural phenomenon that can cause the deterioration of earthen materials. The germination of seeds in earthen walls or roofs, where they have been deposited by the wind or by animals, is not unusual; seeds germinate there just as they would in any soil. As a consequence, the action of the growing roots would break down the earthen components or would cause moisture retention, which in turn causes damage to the structure (de Teel Patterson and Look 1978). On the other hand, the lichens may produce acids that could also be deleterious.

Human and animal activity includes human mechanical damage and visitation-induced abrasive wear and tear, inadequate or noncompatible interventions, lack of maintenance or abandonment, and insects-induced or animal mechanical damage.

During the lifetime of earthen buildings, repairing is common and the usage of incompatible materials for repair or treatment could lead to the buildings' deterioration. For instance, the use of high proportions of Portland cement to repair earthen buildings can cause the structure to crack and crumble owing to differences in thermal expansion between the cement and the earth materials, as well as to salt crystallization or to the dissolution cycles of the salts in the cement (Rainer 2008). The replacement of wooden lintels

or doors with steel ones could cause the earthen wall to twist, since the steel lintels are more rigid than the earth ones (de Teel Patterson and Look 1978).

Another common cause of the deterioration of earthen buildings is their lack of maintenance, or even their abandonment. For instance, after an excavation, the earthen buildings in archaeological contexts are subject to extreme changes of environment, which disturb the equilibrium that the structures have reached over a long period of burial. Thus they become more vulnerable to environmental factors of decay, and rapid deterioration could ensue if no right measures are taken for maintenance to be performed (Rainer 2008).

Animals, birds, and insects often live in earthen buildings, burrowing and nesting in walls or foundations, and this undermines, even destroys the structural integrity of earthen buildings. Termites attack the wood members of such buildings (e.g., floors, windows, and roofs, as well as any other cellulose material mixed with the building material), causing physical damage, and sometimes even the destruction of an entire building (de Teel Patterson and Look 1978).

External factors that lead to the deterioration of earthen buildings include earthquakes and other natural disasters (e.g., floods). As adobe buildings have thick and massive walls of low strength, it is possible for the stress caused by an earthquake to exceed the tensile capacity of the adobe material, leading to the formation of cracks, and even to collapse (Leroy Tolles et al. 1996).

It should be noted that it is usually the combination of many factors that prompts the deterioration of earthen materials. Depending on a condition assessment that established the level of deterioration of earthen structures, conservation intervention could be necessary. For instance, for archaeological sites, some common conservation practices include taking preventive measures during excavation, building wall caps and temporary or permanent shelters, reconstructing, backfilling, burial and site stabilization, removal of architectural elements and relocation, and monitoring and evaluation. For built earthen structures, some conservation common practices include cleaning and desalination, grouting,

application of consolidants and adhesives, performing surface treatments, as well as, monitoring and evaluation (Oliver 2008a, 2008b).

Deterioration of Metals

STAVROULA GOLFOMITSOU

University of Gothenburg, Sweden

Corrosion is defined as the chemical alteration of metals due to interactions with the environment, and is considered a natural process. Except for noble metals such as gold and platinum, all metals will corrode under certain conditions—most typically via electrochemical oxidation processes that produce oxides or other more stable metal compounds (Jones 1996). Corrosion results in irreversible changes to the chemical, physical, and mechanical properties of a metal. The effects of these chemical changes can take a wide variety of forms, from the partial obscuring of the metal surface with corrosion products, to the complete alteration of entire objects (see corroded iron object in Figure 1). While these processes are typically thought of as damaging, the term corrosion is used to describe all reactions of a metal with its environment, many of which might not have adverse effects. Some oxidation processes, for example, lead to the formation of a protective surface oxide which can be desirable and acts protectively. Yet, metal corrosion—the extent and form of which is dependent on several interrelated parameters—in many instances can and does cause severe damage and can lead to loss of an object.

Humans first exploited native metals such as gold, silver, and copper. As knowledge and technologies developed, the number of metals discovered and utilized increased, as well as the ability to combine metals to create alloys. Alloying can improve working and performance properties such as fluidity for casting, or hardness. Today, the metal alloys produced by industry are complex and engineered to meet a wide range of specifications, among which corrosion resistance is a key priority. However, in addition to chemical composition, the way a metal object is manufactured also affects physicochemical properties and hence its corrosion behavior: for example, cast

iron objects are less susceptible to corrosion than wrought iron.

The main factors affecting corrosion are: composition and microstructure of the metal/alloy; the environment (including type, chemical composition, temperature); and the nature of the interface between the metal and the environment where the reactions are taking place (Shreir, Jarman, and Burstein 1994, 1–7). The number of diverse influencing factors and electrochemical processes involved render corrosion science a particularly complex area of study. Nevertheless, a simplified general model for corrosion can be described as follows: most corrosion processes take place through electrochemical reactions between the metal and its environment in the presence of an aqueous or solid electrolyte. During electrochemical processes, anodic and cathodic half-reactions take place. The metal, which plays the role of the anode, loses electrons and becomes oxidized (i.e., its valence changes from zero to a positive value (see reaction 1). The electrons released during the anodic reaction are consumed by a cathodic reaction such as oxygen reduction (2a) or hydrogen evolution (2b). Byproducts of these reactions form metal compounds known as corrosion products.

A number of tools exist that aim to predict whether corrosion could take place and, if so, how quickly this might happen. These draw on two sets of information: (1) thermodynamic methods—used to determine the tendency of a metal or alloy to corrode; and (2) kinetic methods such as the corrosion potential—used to determine the rate at which this will take place. These two aspects are key in determining the likely incidence of corrosion. While an object can be exposed to conditions which could lead to corrosion, the rate at which these reactions proceed may be so slow as to result in negligible

(a)

(b)

Figure 1 (a) Unidentified corroded iron object found during excavations at the Apedemak temple at the Royal City of Meroe in Sudan. The metal has been completely mineralized. (b) X-ray imaging of the object showing the extent of corrosion, with a limited metal core evident from the light area (scanning parameters 120 kV, 4.1 mA, 180 ms). Photos by author.

alteration of the metal. Corrosion theory, though well-developed, is still unable to make accurate predictions regarding the corrosion rate and expected “lifetime” of metal objects due to the multitudinous factors affecting them.

Governing factors

Oxygen and humidity are predominant factors affecting corrosion, but other chemical elements might also trigger corrosion reactions. These elements vary for different metals. For example, the chlorides, found in seawater, coastal air, and polluted groundwater, accelerate the corrosion rate of metals such as copper, iron, zinc, and aluminum. Silver is affected by sulfur compounds, while lead is strongly affected by organic

acids. Similar metal objects exposed to different environments will corrode in different ways.

The type of environment to which a metal object is exposed also has a significant impact on corrosion. In a pure, pollution-free environment, the corrosion rate of a metal will be low in comparison to that of a polluted environment. The main factors affecting corrosion in rural environments are the quantity and frequency of rainwater arriving at the metal surface, humidity and temperature fluctuations, winds, and the presence of corrosion active agents such as chlorides or sulfates. Dust particulates are also important. When deposited on the metal surface, they form a hygroscopic layer that attracts water molecules from the atmosphere. By contrast, urban atmospheres contain pollutants from car exhausts and industrial outputs that result in high levels of nitrogen oxides (NO_x), ozone (O_3), sulfur dioxide (SO_2), and ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$) (Leygraf and Graedel 2000). These react with moisture and other elements to form compounds such as acids that accelerate corrosion processes.

Oxygen concentration, water content, pH, salinity, and redox potential are but a few of the factors that will determine the corrosivity of soil in burial environments. Some of these parameters vary widely within a short range. The closer a metal object is to the surface, the higher the oxygen content, for example. Aerated acidic soils with high moisture and salt contents are generally corrosive. The resistivity of the soil can be used as a measure of its corrosivity, with low resistivity being indicative of high corrosivity of the soil (Jack and Wilmott 2011). In an underwater environment, where there are plenty of corrosion accelerants such as water, chlorides, and sulfates, corrosion will be fast. Here the most significant factors are salinity, concentration of dissolved oxygen, pollutants, biological factors, and the presence of minor elements, which change depending on depth, ocean currents, and temperature. In addition, gases such as carbon monoxide (CO) and carbon dioxide (CO_2) will also affect corrosion. Water hardness is determined by the presence of calcium (Ca) and magnesium (Mg) ions, which can form carbonates. The formation of a layer of calcium carbonate (CaCO_3) across the surface of an object can act as a protective barrier, limiting the amount of oxygen accessing the metal and

thereby slowing down the overall reactions. In static conditions, metals reach a phase of equilibrium with their environment, causing corrosion reactions to slow down. However, any rapid change in environmental conditions can result in accelerated corrosion. A typical example of this is the effect of excavation, during which the equilibrium between the metal and its environment is disturbed. This, coupled with exposure to increased levels of oxygen, fluctuating levels of humidity and temperature, and other pollutants, will trigger further corrosion processes.

Corrosion forms

The outcomes of corrosion vary. A common misconception is that if a metal shows no visible sign of corrosion, surface oxidation has not occurred. Many metals oxidize rapidly when exposed to oxygen in the atmosphere. In the case of copper and copper alloys, the most common corrosion formed is copper oxide (cuprite; Cu_2O), whereas, in the case of iron and steel the corrosion products are oxide-hydroxides (FeOOH). Air-formed oxide layers are not visible until they are thick enough to cause surface alterations, noted by darkening or dulling of the surface. Oxide layers can also act protectively, slowing down corrosion (passivation). When corrosion is ongoing, it is called active.

As corrosion develops, the oxide layers can be transformed into other compounds, altering not only the composition of the surface, but also the physical properties of the metal/metal alloy. Corroded copper and iron alloy objects are more voluminous than the originals due to the compounds formed.

Preservation of the shape and original surface of a metal object depends on the type of corrosion. Corrosion can be uniform, covering the surface with the same compounds. This type of corrosion is the least deleterious as it tends to preserve the characteristics of an object's surface, and is typical of those exposed in the atmosphere. Localized corrosion can be detrimental to the metal/metal alloy. Galvanic corrosion, for instance, takes place when two metals are in contact, and the more active metal becomes the anode and corrodes, while the noble metal acts as the cathode and is left intact (Cicek and Al-Numan 2011).

Similarly, selective corrosion occurs when one metal in an alloy is preferentially corroded, either because it is more active (e.g., dezincification) or because it reacts with elements in its immediate environment (e.g., decuprification). In alloys, intergranular corrosion occurs around the grain boundaries within an alloy, while transgranular corrosion transverses the grains. Filiform corrosion can take place when a metal is covered with a coating, and crevice corrosion can result when only part of the metal is covered with another material. The most severe form is pitting corrosion, which involves the development of pits which vary from shallow and wide to deep and narrow. The severity of deterioration is due to the creation of a micro-environment within the pit, with autocatalytic reactions taking place which are hard to stop. Differential aeration, meaning variable oxygen exposure to different parts of the metal's surface, results in the development of an electrochemical cell and formation of anodes and cathodes.

Outlook

Corrosion might compromise metallic heritage, but the original surface of objects is often preserved within corrosion layers. A lot of information about the life history of an object can be extracted from a study of its corrosion products. Since corrosion types and corrosion products are a direct result of the reactions between the metal and the surrounding environment, they are often indicative of the conditions to which a metal has been exposed. An example is the presence of corrosion products such as sampleite ($\text{NaCaCu}_5(\text{PO}_4)_4\text{Cl}\cdot 5\text{H}_2\text{O}$)—the outcome of reactions between copper and decomposing bodies in burials (Scott 2016). This part of corrosion science is yet to be utilized in archaeological research. The extended number of alloys in combination with all the above-mentioned parameters make investigation of archaeological objects a complex but fascinating field.

Deterioration of Mosaics

STEFANIA CHLOUVERAKI

Technological Educational Institute of Athens, Greece

In the conservation literature deterioration of mosaics refers to a wide variety of weathering mechanisms and conditions that occur on the mosaic surface or the underlying foundation layers, resulting in the weakening of its physical state. While in the past only the decorated surface was valued, today mosaics are perceived and treated as a composite architectural surface, which is an integral part of the monument (see CONSERVATION OF MOSAICS). When seen in their original context, mosaics are composite structures comprising of a series of foundation layers, which support the tessellated surface. The materials used in the construction of mosaics vary according to the geographic location, historical period, function in the building (i.e., floor or wall), and level of craftsmanship. Lime mortars with various types of aggregate are used for the foundation layers with a great diversity in composition and thickness. The tesserae are usually made of sedimentary stones, mainly limestone, while ceramic, glass, faience, or shells are used occasionally. Deterioration of mosaics refers to all the weathering forms and processes that affect the mosaic as a whole or any of the aforementioned constituent materials.

The first attempt to define and categorize the causes and types of deterioration of ancient and historic mosaics was made at the first meeting of specialists in 1977 at ICRROM, which gave birth to the International Committee for the Conservation of Mosaics (ICCM, www.iccm-mosaics.org) and produced the first publication on the deterioration and conservation of mosaics (Selvig 1978). Mosaic deterioration was examined in two broad categories: the in situ mosaics and the mosaics in a museum context. Amongst the main causes of destruction and loss of in situ mosaics acknowledged in this first meeting, were agricultural

activity and construction works, followed by mishandling and lack of management. Deterioration processes were attributed to mechanical, thermal, biological, and chemical stresses acting alone or more often in combination. Careless excavation, administrative delays, and lack of experienced personnel were related to the severe damage and extensive loss of detached mosaics. Moreover, the detrimental effects of inappropriate materials and techniques during the detachment of mosaics and their transfer to inadequate new supports were discussed (Bassier 1978; Veloccia 1978).

In the following years ICCM organized a series of triennial conferences, the proceedings of which have recently become available online (<http://iccm-mosaics.org/product-category/iccm-proceedings/>) and constitute the main source of information on issues concerning the deterioration, conservation, and management of in situ mosaics.

A recent literature review on the deterioration and conservation of mosaics in situ (Piqué et al. 2008) reports four broad categories of deterioration factors that affect mosaics throughout their long history of life: (a) intrinsic qualities, (b) historic events, (c) environmental impact, and (d) human actions. The types of deterioration that occur in mosaics can rarely be attributed to a single event or a specific deterioration agent. A combination of events and the synergistic interaction of various agents are usually responsible for the current condition of mosaics. However, the classification of deterioration agents and weathering forms facilitates the examination, documentation, and better understanding of the deterioration mechanisms.

The intrinsic qualities of the original structure refer to its susceptibility to deterioration, which is related to inherent instability of the foundation or poor physical and mechanical properties of the materials employed in the construction of mosaics. Inherent problems include: weakening and failure of mortars due to poor material selection and incorrect mix proportions, erosion of stone tesserae related to their mineralogical characteristics (see DETERIORATION OF STONE

AND PETROGLYPHS), alteration of glass tesserae related to their composition (see DETERIORATION OF VITREOUS MATERIALS), biological colonization on porous tesserae, and differential subsidence and fracturing caused by underlying architectural features that create voids or inconsistencies in the substrate.

In the category of historic events are included natural disasters, reuse or abandonment of the building, burial, and excavation. The effect of historic events in the deterioration of mosaics can be rarely traced with accuracy. Ancient conservation interventions, such as the reintegration of lacunas with mortar, tesserae, or slabs, are often found in ancient mosaics, indicating that deterioration processes were underway during the initial use of the building. In the Near East several mosaic floors depicting human and animal representations were defaced during the Byzantine iconoclasm, in the eighth and ninth centuries, however, the losses were reintegrated with tesserae or mortar which stabilized the mosaic surface and prevented further loss.

Natural disasters, mostly earthquake, fire, and flood, force intense mechanical as well as thermal stresses, which result in severe deterioration and large-scale losses. The impact of major earthquakes, which have occurred in recent times, has been documented in great detail in mosaics that were already exposed at the time of the tectonic activity. Loss of tesserae, fracturing, detachment of the preparatory layers of mortar, and finally collapse of mosaic sections are some of the most significant effects of earthquakes in wall mosaics. Moreover, as a result of the loss of structural integrity, water percolates through the roof and the walls of the building initiating leaching of lime mortars, transfer and crystallization of soluble salts, or freeze-thaw cycles. Mosaic floor pavements are usually less affected by seismic activity, showing mostly structural subsidence and fracturing caused by the collapse of heavy architectural elements over them.

Abandonment and the subsequent degradation and collapse of the architecture also results in severe mechanical damage of mosaic pavements or the complete destruction of wall mosaics. The collapse debris and the gradual deposition of soil over the centuries cover

the mosaics, which remain under burial until they come to light by archeological excavation, construction works, or agricultural activities. Under burial, mosaics suffer damage due to the mechanical loads of the debris, geophysical disruptions of soil, agricultural activity, site erosion, freeze-thaw cycles, organic acids, and other soluble substances present in the soil, root penetration, microorganisms and activity of burrowing invertebrates and mammals (Stewart 2004). However, they gradually reach equilibrium with the burial environment and may remain in a stable condition for a long period of time. Archeological excavation or accidental discovery of mosaics can be beneficial or detrimental to the mosaics depending on the provisions made for their care and conservation during and after excavation. The systematic detachment of mosaics during the postwar period followed by their abandonment in depots or their mounting in reinforced concrete slabs was responsible for the severe deterioration or the complete destruction of numerous excavated mosaics (Bassier 1978; De Guichen and Nardi 2008).

Upon excavation mosaics are rapidly exposed to a completely different set of environmental parameters and a series of deterioration processes are activated. Temperature fluctuations are associated with the differential expansion and contraction of the layered mosaic structure resulting in fracturing and loss of cohesion or detachment between layers. In the presence of water, thermal fluctuations can also activate freeze-thaw and salt crystallization cycles. The effects of these mechanisms on different types of stone and mortars can vary significantly depending on their physical and mechanical characteristics. Soluble salts migrate through the porous mortar layers towards the tessellated surface, which acts as the interface between the mosaic and the atmosphere. Salt efflorescence occurs in the interstices between the tesserae causing disaggregation of the bedding mortar and gradual loosening and loss of tesserae, while sub-efflorescence results in fracturing, exfoliation, flaking, or scaling of the stone (see DETERIORATION OF STONE AND PETROGLYPHS).

The accumulation of soil in the interstices between tesserae, or other irregularities of the surface, retains moisture and provides a fertile

ground for the growth of microorganisms. The type and the rate of biological growth depend on the microclimate and the nature of the stone, which often provide a source of nutrients for microorganisms. Lichens, algae, fungi, and cyanobacteria are the most common organisms found on mosaics. They obscure the mosaic surface and can alter the physical and chemical characteristics of the mortar and tesserae, resulting in increased susceptibility to other types of deterioration.

The rooting of higher plants on or around the mosaic surface is another major threat to in-situ mosaics. Penetration of roots into the tessellatum through existing fractures causes detachment and loss of tesserae, while the expansion of roots into the foundation weakens the entire mosaic structure and results in loss of cohesion and detachment between the underlying mortar layers, often observed on the surface as bulging.

The last category of deterioration agents refers to the human action that is thought to have the greatest impact in the current condition of mosaics. Neglect, mismanagement, lack of systematic maintenance and preventive measures, use of inappropriate conservation materials and methods, and lack of trained personnel are the main problems related to human action. Uncontrolled and increased visitation is known to have caused significant damage to mosaics. Abrasion of soft and already deteriorated tesserae, dislocation and loss is often observed but rarely accounted. The lack of regular inspection and maintenance of mosaics has been a major topic of discussion amongst conservation professional and site managers over the last two decades, yet only a few sites have developed plans for the long-term maintenance of mosaics after the completion of conservation. Last, but not least, recent political conflicts in the southeastern Mediterranean have triggered vandalism, illicit excavation, and trade of mosaics. Although the problem has been acknowledged, the extent of destruction remains unknown.

The variety and complexity of deterioration processes and alterations or conditions that occur in mosaics have lead to major confusion and difficulties in the communication between scientists, conservators, and practitioners. As a response to this problem a glossary has been developed which provides a valuable tool that enables conservators

to use a common language in the description of mosaics and the documentation of deterioration patterns (Alberti et al. 2013), while an updated literature review on the causes of deterioration is soon expected (Roby and Demas 2012).

Deterioration of Stone and Petroglyphs

IOANNIS IOANNOU

University of Cyprus, Cyprus

Anyone who has looked closely at a stone monument should be able to identify with the deterioration (see DETERIORATION) of stone and petroglyphs. While there are indeed a number of stone monuments that seem to be little affected by centuries of exposure to the environment, the majority of them are subjected to gradual deterioration, despite how well they are looked after. Thus, the deterioration of stone and petroglyphs constitutes a major international problem of considerable practical interest, with cultural and economic dimensions, which has been attracting the attention of researchers for quite some time (e.g., Schaffer 1932; Honeyborne 2006; Thompson and Dorn 2017).

There are several causes for the deterioration of stone and petroglyphs, each one bearing a recognizably different effect. Some of these causes, such as earthquakes, floods, and vandalism, are sudden and rapid in their effect. Others are slow and more insidious. Such causes include chemical attack, atmospheric pollution, biodeterioration, and salt crystallization. This entry focuses on the most common causes. The aim is to provide a comprehensive and balanced account of these causes which will allow for a better understanding of the problem per se in order to address it more effectively (see CONSERVATION OF STONE AND PETROGLYPHS).

The most common cause of stone and petroglyph deterioration is probably the crystallization of salts. There are many ways in which stone and petroglyphs can become contaminated with salts. In fact, water moving inside stone may contain various soluble salts originating from the atmosphere or the soil or contained within the material itself and/or neighboring materials (e.g., mortar in contact with stone). Other important sources of salts include biological activity or even

some cleaning and conservation (see CONSERVATION) treatments. Unlike water, salts do not evaporate upon drying. Instead, they crystallize either on the surface (efflorescence) or within the pores (cryptoflorescence or subflorescence) of the material. While the former mode of crystallization is generally unsightly but harmless for stone (though it may affect petroglyphs), cryptoflorescence can generate stresses that are sufficiently large to cause localized fragmentation of the material (e.g., Scherer 2004). The precise location at which salts crystallize depends on the rate of drying, the material itself, and the nature of the salts. Nevertheless, it is not unusual for both forms of florescence to occur together (Honeyborne 2006). It is worth noting that the pore structure of a stone plays an important role in determining its resistance to salt crystallization. Fine-pored stones are generally more susceptible than coarse-pored ones, although the latter may also experience high crystallization stresses, once the coarse pores are nearly filled with salt (Scherer 2000).

In coastal and arid climates, honeycomb or alveolar weathering may develop on granular rocks, due to salt crystallization (Figure 1a). Initially, this kind of stone and petroglyph deterioration may form pits and recesses; however, as it develops, the pits may broaden and deepen to form a network of adjacent and/or connected cells across the stone surface. This causes the deterioration of engraved or inscribed surfaces through lateral and/or internal recession (Paradise 2014).

Atmospheric pollution also contributes to the deterioration of stone and petroglyphs (Figure 1b). The main atmospheric pollutants are acidic, sulfur-based gases (e.g., SO_2) and carbon dioxide (CO_2). These are capable of dissolving in rainwater to form acid rain. The latter reacts chemically with calcareous materials (e.g., limestones and marbles), leading to their slow erosion. While stones consisting wholly or even partly of calcium carbonate are the ones mostly affected by atmospheric pollution, non-calcareous stones (e.g., sandstones) may also be affected due to the absorption of products

Figure 1 (a) Honeycomb or alveolar weathering of stone due to salt crystallization (Kronborg Castle, Helsingør, Denmark, 2008). (b) Deterioration due to atmospheric pollution (Charles Bridge, Prague, Czech Republic, 2012). (c) Deterioration of a stone façade along its soft beds (Nicosia within the walls, Cyprus, 2006).

resulting from the decomposition of neighboring calcareous materials. Calcareous sandstones (i.e., sandstones in which quartz grains are cemented together by calcite) are particularly attacked by sulfur-based acids in the atmosphere. In fact, these sandstones weather more severely than limestones in regions of high air pollution, since the dissolving of a small amount of calcite will release many quartz grains (Honeyborne 2006). Thus, in the presence of heavy acid rain, the surface of a calcareous sandstone may powder away. Even in the absence of heavy rain, however, the acids may attack some of the calcite in a calcareous sandstone, converting it to the more soluble gypsum. The latter is drawn towards the surface in solution and is redeposited upon evaporation of the moisture and drying of the stone. This leads to the formation of a weak skin layer close to the surface of the stone, which peels off when the temperature fluctuates.

Temperature fluctuations are responsible for the development of thermal stresses on the surfaces of stone and petroglyphs. In regions where these stresses can be extreme (e.g., deserts where there is a noticeable diurnal temperature difference), the heated surfaces may expand at rates much faster than the cooler substrate interior. This spontaneous and/or long-term differential expansion (and contraction upon cooling) can initiate surface spalling or exfoliation, thus contributing to the deterioration of stone and petroglyphs.

Deterioration due to frost action may occur by moisture freezing inside the pore structure of a stone. Frost damage mostly appears in the form of cracking; usually it involves the separation of a wafer or lens-like piece of stone (i.e., flaking) from the outer most exposed surface of the material (Honeyborne 2006). This kind of damage may lead to disfigurement of a petroglyph, but it will

not generally affect the functionality of a stone, even though tourists visiting the site may exacerbate the process by touching or pulling the flake from the substrate. On other occasions, however, the stone may be rendered useless by the direct action of frost. This normally occurs when cracks radiate in many directions, thus reducing the material to smaller fragments. The latter form of damage mostly affects coping and cornice blocks and balusters, which are exposed to cold winds and clear night skies. As with salt crystallization, the pore structure of a stone has a similar effect on its resistance to frost action.

The growth of living organisms on stone can be both a blessing and a blight (Doehne and Price 2010). While the presence of lichens and creepers, such as ivy, may contribute an air of age and romance to stone monuments, and provide thermal stability, thus reducing thermal stresses, on other occasions, biological organisms may enhance deterioration caused by physical processes by inducing physico-chemical changes. For instance, filamentous organisms may extend existing structural and other flaws, while biological assemblages may expand and contract upon wetting/drying, thus exerting damaging stresses on the microstructure of stone and on the petroglyphs beneath. Furthermore, the secretion of enzymes and acids by biological microorganisms may contribute to the biochemical deterioration of stone and petroglyphs. It is therefore necessary to find the right balance between appearance and durability in the case of biological growth. In fact, the topic of biodeterioration has gained increasing attention since the turn of this century. Many researchers nowadays focus on the effect of biofilms on the thermal, hygric, and mechanical properties of stone and the possibility of enhancing deterioration by increasing the duration of surface wetting and providing a source of organic acids and complexing agents (Doehne and Price 2010). At the same time, other researchers (e.g., Hess et al. 2008) work on certain biological processes that may potentially offer protection to stone and petroglyphs in the long term: for example, bacterial biomineralization of calcium carbonate and development of oxalate minerals. This strongly suggests that the effect of living organisms on stone and petroglyphs is still very much open to discussion among the scientific community, with

proven negative and positive aspects entering the equation.

Besides the above well-recognized causes of deterioration of stone and petroglyphs, problems associated with material-inherent defects are also common. Such defects (e.g., soft beds, “vents,” and “shakes”) usually become apparent only after the material has been exposed to aggressive environmental conditions (Figure 1c). Sedimentary rocks, in particular, may contain beds of different structure or composition possibly due to geological changes taking place during their formation (Schaffer 1932). These differences may result in weaker areas that weather faster; in practice, this will show up as uneven weathering. While in ashlar stone, deterioration associated with soft beds is of little importance, except in terms of aesthetic appearance, in projecting or free-standing features it may lead to the loss of large masses of material, thus rendering the structure dangerous. The presence of minute fissures (i.e., “vents” and “shakes”) may also have a detrimental effect on stonework in general and petroglyphs in particular. “Vents” are fissures which comprise a source of weakness; these may not be readily visible in freshly quarried stone blocks. However, they become apparent after a period of exposure to aggressive environmental conditions. “Shakes,” on the other hand, are calcite veins which have no harmful effect on stone. They are often observed on limestone and they frequently stand out in relief from the weathered surface of the stone (Schaffer 1932). It is worth pointing out that the effects of salt crystallization and frost damage are different on stones that have marked weaknesses along their natural bedding planes.

Despite the fact that the deterioration of stone and petroglyphs has been well studied over the years, and irrespective of the wealth of available information, no claim can actually be made that finality has been reached, at least on most aspects of the problem. Existing work shows that much remains to be done in studying the properties of various available stones, and in correlating these properties with the observed behavior of the materials in practice. One of the difficulties until fairly recently has been the fact that related work in the past was mostly undertaken by individual investigators. This highlights the need for interdisciplinary thinking during the study of the deterioration of stone and petroglyphs.

Such an approach has in fact been emphasized in recent years, following the recognition of the inherent complexity of the problem, which often combines physical, biological, and chemical processes under the control of geological and environmental factors (Viles et al. 1997). It is therefore anticipated that in the near future, knowledge regarding the deterioration of stone and petroglyphs will be further enriched, to take into account the combined effect of rising atmospheric pollution levels, changing climatic conditions, and inherent material properties. This will undoubtedly allow the development of more effective conservation treatments and practices for the better care and protection of stone and petroglyphs.

Deterioration of Vitreous Materials

N. ASTRID R. VAN GIFFEN and STEPHEN P. KOOB

Corning Museum of Glass, USA

Glass and other vitreous materials are found at archaeological excavations in a variety of conditions. The condition can range from pristine, where no deterioration is visible, to so heavily degraded that practically all the glass has been transformed into corrosion products. Glass can also deteriorate in the atmosphere. In both cases, the chemical and physical properties of the environment, especially moisture, and the composition of the glass itself are the main factors that determine the rate of deterioration.

Deterioration during burial

Deterioration of the glass surface during burial is generally known as *weathering* and the deteriorated area as a *weathering layer* or *weathering crust*. Water is the primary cause of deterioration of glass; therefore, glass found in dry soils is generally better preserved than glass found in moist soils. The exposure of glass to moisture causes alkali ions (sodium oxide and potassium oxide) in the glass to be slowly leached out and replaced by hydrogen ions. This leached layer is referred to by several different terms: alkali-deficient layer, silica-rich layer, or hydrogen glass. In general, as the proportion of alkali to silica increases, more alkali is leached; potassium is leached at a greater degree than sodium.

Frequently, the weathering crust is found to have a laminar structure, with individual parallel layers ranging in thickness from less than 1 μm to about 25 μm . The deterioration process occurs in a cyclic manner, creating distinct layers within the weathering crust. As additional layers

form, the crust gets thicker and thicker. The final weathering crust can vary in thickness from microscopically thin to so thick that it can easily be seen without a microscope. Although the chemical processes of glass deterioration have been extensively studied, they are not yet entirely understood and cannot be predicted.

In some cases, the alkali-deficient layers protect the remaining glass from further deterioration; they limit access of water to the remaining glass and thus slow down the formation of new layers. Whether the crust is protective or not depends primarily on the composition of the glass and the pH and temperature of the leaching solution. Glass is fairly resistant to acids, and even highly acidic environments will do little damage to the glass unless fluoride or phosphate ions are present. Alkali environments are much more damaging because the molecular framework of the glass, the silica network, is attacked and broken down, eventually causing the total dissolution of the glass. Higher temperatures speed up the deterioration process. Localized differences in the burial environment can result in variation of the extent and appearance of weathering of glass found on the same site, even within a single piece of glass.

Importance of preserving the weathered surface

Unlike corrosion on metals, glass corrodes from the surface inward, making the weathered surface an integral part of the object because it retains the shape of the original surface even if the composition has changed. Details such as incised decoration, the thickness of the glass, and marks relating to the production or usage of the object can only be preserved if the weathering crust remains intact. These types of details contain information that is quite valuable for the technical, art historical, and historical interpretations of the object.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0179

Preservation of surface details is not the only reason to ensure that the weathering remains whole. The removal of weathering often reveals a very irregular and often pitted surface because air bubbles and debris trapped in the glass during production are exposed as a result of the degradation. The exposure of such a surface can result in misinterpretation of the original appearance of the object and is aesthetically unappealing.

Finally, there is the aesthetic appeal of the weathering itself, especially iridescence, which has become so associated with archaeological glass and is much valued for its beauty.

Visual appearance of deterioration

The appearance of weathered glass can vary extensively. The visual effects of degradation most commonly found on excavated glass are dulling, iridescence, opaque weathering, pitting, cracking of the surface, discoloration, and a total loss of glassy nature.

Dulling refers to a loss of original clarity and transparency that is quite distinct from haziness caused by scratches or stains. It is closely related to *iridescence*, which is a rainbow-like effect on the surface of the glass similar to a thin layer of oil on the surface of water. Both dulling and iridescence are caused by changes in the composition of the surface of the glass altering the refractive index. The many thin alternating layers of air and weathered glass that make up weathering crusts cause interference between reflected rays of light, leading to iridescence.

Opaque weathering also has a laminar structure, but has a much larger number of layers. These layers may be densely held together and penetrate the entire surface or they may be laminating and superficial and easily disturbed. This type of weathering is characterized by opaque areas, usually white, on the surface, gradually penetrating deeper into the glass; this is generally referred to as *opaque* or *opalescent* weathering. At more advanced stages, the color can be black or brown or even a mottled polychrome. The incipient stage is sometimes referred to as milky weathering because of small spots or streaks of white. At the most extreme stage it is termed

enamel-like weathering and is present as a thick covering varying in color.

Pitting can occur when the deterioration starts at a specific point either on or just below the surface, sometimes creating concentric circles around the starting point. When the weathering is lost, a hole or pit is left in the surface of the otherwise undamaged glass. Pitting often occurs simultaneously at individual sites throughout the surface of a fragment. Weathering from individual starting points can later grow into one another.

Cracking of the surface and within the weathering crust itself can be caused by shrinkage of the alkali-deficient layer due to temperature and humidity changes. Often the cracking does not become visible until some time after the glass has been excavated. This is especially true for glasses buried in wet soils.

Discoloration of the glass can be found in combination with any of the above-mentioned types of weathering and is caused by the migration or alteration of coloring ions and other trace elements. The ions can be leached out of the glass or be taken up by glass from the environment. Iron and manganese cause the weathering crusts to blacken, and contact with copper corrosion products can cause green staining. Yellow-brown iron rust stains are also very common. Certain ions, most notably manganese and copper, may change color through oxidation.

A *total loss of glassy nature* occurs when glass is so badly deteriorated that it exists only as a mass of silica gel and has a sugary appearance which is sometimes difficult to identify as glass.

Combinations of several of these manifestations of glass deterioration are usually found on a single object. The extent of the degradation can also differ from one area on an object to another. The thickness of the weathering crust can vary greatly, depending on the chemical stability of the glass and the aggressiveness of the burial conditions. In extreme cases, corrosion products may have completely replaced the original glass. Underneath the weathering crust the so-called *glass core* retains the original composition and color of the glass.

Atmospheric deterioration of glass

Atmospheric deterioration of glass is a type of glass deterioration that looks very different than the degradation that occurs during burial. In fact, it rarely occurs on archaeological glass. However, the main factors that determine the rate and severity of deterioration are the same, namely the composition of the glass and the environment surrounding it, especially moisture. Water from the air is attracted to and absorbed by the surface of the glass leaching out alkali ions. Alkalis accumulate on the surface, creating a localized high pH environment that dissolves the silica network of the glass, which in turn frees up more alkalis that continue the deterioration process.

Koob (2006, 118–125) uses five stages to describe the progress of the deterioration, some of which may occur simultaneously:

1. During the *initial stage* the presence of alkalis on the surface give the glass a hazy or cloudy appearance. When the humidity is lower (below 40%), the alkalis will form fine crystals. When the humidity is higher (above 55%), tiny droplets will form and may even run down the glass, a symptom known as “weeping” or “sweating.” At moderately low humidity (30–50%), alkali crystals and droplets may be present at the same time. A glass in the initial stage can be washed to remove surface alkalis which will remove the cloudy or hazy appearance and slow down the deterioration process.
2. The second stage, known as *incipient crizzling*, involves the same symptoms as the first stage, but at this point the haziness can no longer be washed away. The glass may look perfect when wet, but as it dries the haziness returns. In addition, close examination under low, raking light will reveal tiny silvery lines in certain areas of the glass. These are very fine cracks caused by the cumulative loss of alkali and the breakdown of the silica network.
3. *Full-blown crizzling* is when the cracking of the surface of the glass has progressed further and can easily be seen without a microscope. The cracking goes deeper into

the glass in stage 3 than in stage 2. If the crizzling has not affected the entire surface, it may be accompanied by symptoms of stage 1 or 2. The deterioration of an object may be irregular because of localized microclimates, such as in the interior of a bottle.

4. In the *advanced crizzling* stage, there is distinctive cracking of the glass, which is so deep that the surface is lost. Often flakes of the glass surface can be found around the base of the object.
5. The *fragmentation stage* is reached when the cracking has become so deep that the object loses its structural integrity and falls apart. This may happen with or without any inside intervention such as regular handling.

It is nearly impossible to predict how fast an unstable glass will deteriorate. Some very unstable compositions may fall apart within years of manufacture, or the deterioration may continue for centuries. Progression from one stage to the next may also occur rapidly or over a prolonged period.

Atmospheric deterioration is found mostly on glass with a less than stable composition, although under certain conditions almost any glass will deteriorate. Glasses most likely to have unstable compositions generally date to time periods when glassworkers were experimenting with new glass compositions. One prime example is Venetian glass from the sixteenth through nineteenth century when glassworkers were attempting to create *cristallo*, glass with the clarity of rock crystal. In the process they overpurified the ingredients, lowered the amount of stabilizers, primarily lime (CaO), and increased the alkali content. The resulting glass melt was easy to work with at lower temperatures and produced brighter and completely colorless glass, but unfortunately it is also less durable.

In the past, this type of deterioration was commonly known as glass disease, although that term has fallen out of favor recently. Crizzling and weeping have also been used to describe the phenomenon, but they more accurately describe the symptoms at various stages of the deterioration process.

Deterioration of Waterlogged Materials

HEATHER MCKILLOP

Louisiana State University, USA

Waterlogged materials often enhance knowledge of the past by providing spectacular preservation of materials not normally found at archaeological sites. Deterioration of waterlogged materials occurs in the matrix of archaeological sites (and during use prior to deposition), accelerates when removed from the waterlogged matrix, and continues during study and after professional preservation. The ability to study waterlogged materials presents problems because they deteriorate rapidly when they are removed from their context. Salt-waterlogged materials add additional deterioration issues. Wood, cloth, low-fired pottery, metal, and other materials deteriorate in different ways, sometimes precluding their study until they are conserved because the surface is altered. Long-term conservation of waterlogged materials presents additional questions so that decisions often are made to select a small percentage of artifacts, beyond initial study, for conservation. The goal of conservation is to make the objects chemically stable for study, curation, and exhibit. Three-dimensional (3D) imaging using surface scanners or computed tomography (CT) machines provides a digital record of waterlogged objects when they continue to deteriorate (McKillop 2016).

Deterioration of waterlogged materials at sites

The preservation of specific kinds of materials and their deterioration vary according to the environmental setting of the waterlogged site. Northern European freshwater peat bogs provide a cool, acidic environmental setting where the tannic acid preserves human bodies. Freshwater

peat bogs in England preserved wood, such as the Bronze Age wooden posts and other wooden artifacts at the Must Have Farm site. Salt-water peat bogs in the tropics, such as the Paynes Creek Salt Works in southern Belize (McKillop 2005), preserve wood and other plant materials, but not bone, due to the acidic peat created by red mangroves (*Rhizophora mangle*). Mudslides such as at the Ozette site in Washington state, the United States, have preserved wood and basketry but not bone. Little decay of organic material occurred at the Windover site, where burials were placed 8,000–5,000 years ago, including textiles, wood stakes, gourds, bones, and shell preserved in the peat matrix of the base of the pond (Doran 2002). Wood, bone, and metal preserved in shipwrecks deteriorate in the water and further decay once removed to the air. Waterlogged wood exposed to oxygen at underwater sites decays by boring organisms such as worms.

Wood in wet sites, peat bogs, and underwater deteriorates. There are various stages of decay while the wood remains in situ, identified by the percentage of water in the wood. Over 200 percent water is considered degraded wood. Decay is recorded as class 1, with over 400 percent water, class 2, with 185–400 percent water, and class 3, with less than 185 percent water. As wood decays at wet archaeological sites, there is a sequence of loss of starch, sugars, mineral salts, color, and tannins, leaving the cellulose to support the wood structure. With further decay, the cellulose structure is lost, leaving lignin and water to retain the shape of the wood object, as long as it remains in water. If waterlogged objects removed from sites are allowed to dry, the cell walls collapse, causing shrinkage and warping, and even decay into dust in the absence of cellulose and lignin.

Deterioration of waterlogged materials during excavation

Waterlogged materials deteriorate during excavation if the preserving matrix is removed. Wooden

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0168

buildings, as well as wooden objects and basketry were preserved by a mudslide at the Ozette site, but once exposed the wood began to dry and warp. The coffer dam constructed around La Salle's ship *La Belle* in the Gulf of Mexico to enable excavation contributed to deterioration of the ship by exposing the wood to the air, requiring constant flushing with water (Bruseth and Turner 2005).

Painted decoration on pottery in waterlogged settings can be altered by chemicals in the sediment matrix, such as sulfur. Permanently waterlogged pottery from Wild Cane Cay, an island trading port in southern Belize, was discolored, but the painted decorations were visible, albeit in shades of gray. Calcite-tempered pottery of Warrie Red type was discolored at underwater sites in a salt-water lagoon in Belize (McKillop 2002, 77–86). Original paint color also can permanently disappear quickly with exposure to air, so photo-documentation of any painted pottery or paint on other waterlogged objects, either in permanently waterlogged conditions on land sites or at underwater sites, needs to be carried out. The original color will not appear if the object is immersed in water.

Deterioration of materials during study and preservation

The *Mary Rose* ship was initially conserved by continuously spraying a solution of polyethylene glycol (PEG) at maximum 50 percent with a biocide to hinder biological decay for 20 years (Walsh et al. 2014). The researchers found that acidic salts and iron were able to permeate the wood with PEG conservation. Additionally, PEG can deteriorate to acids over time due to humidity, temperature, bacteria, iron, and natural acids. Polymer preservation is an advance over PEG since the polymer maintains wood integrity, does not decay into acids, and is inexpensive (Smith 2003). Two polymers, guar and chitosan (a biological inhibitor), were used to inhibit acidic and biological decay and prevent deterioration of wooden objects during preservation (Walsh et al. 2014).

Wood, leather, and other organic objects can be saturated with a 10 percent solution of PEG (which prevents the formation of ice crystals that expand and crack the cell walls when the object is frozen), frozen, and then put into a freeze-drier to preserve them long term, although they must be stored in humidity-controlled environments (45–60%). Preservation using the polymer process has been used on wood, china, metal, rope, paper, beads, basketry, and textiles from *La Belle*, with the wooden hull preserved using PEG (Bruseth and Turner 2005). The polymer process does not require humidity or temperature controls and the surface texture and color resemble the original, which is an advantage for display, but the process is not reversible (Smith 2003). Deterioration of waterlogged materials can be slowed by storing them in water. However, the water can contribute to deterioration by increasing the water content within porous materials such as wood. Water fills the inside of cells in the wood structure, softens the wood, and makes the wood subject to exfoliation of the surface, bloating, and fragmentation of the object due to weakness of the wood structure. Waterlogged wooden posts from the Paynes Creek Salt Works stored in water to desalinate them and maintain wood structure for 3D imaging and species identification became bloated and soft, obscuring surface details of the cut ends of the posts.

Deterioration can be slowed by wrapping waterlogged wood in plastic wrap and refrigerating the sample. Deterioration of waterlogged materials can continue after they have been conserved due to cracks or other deterioration that occurred during their usable life. For example, the K'ak' Naab' Maya canoe paddle continues to deteriorate due to cracks in the paddle in antiquity owing to its location in an alternating wet and dry landscape (McKillop 2005).

Waterlogged materials

Iron, copper, brass, and bronze objects corrode in seawater, obscuring the original surface of the item, and further decay from sulfate-reducing bacteria in seawater. X-rays of corroded metals can reveal the outline shape of the original object. If the metal item has completely corroded, a cast

can be made from the interior void space. If the metal is partially corroded, corrosion can be removed by electrolytic conversion (Bruseth and Turner 2005, 132).

Waterlogged wood has the internal cells and other spaces filled with water. Biodegrading by fungi and bacteria is slowed in waterlogged contexts, in contrast to the rapid decay at terrestrial sites. Underwater and terrestrial wet sites vary in the way they deteriorate archaeological materials according to the physical matrix of the site (open water, mangrove peat bog, or land/marine interface, for example), the geochemistry (sulfur, pH values), and available oxygen. Dissolved oxygen in water is reduced in stationary sediment, but increases with water flow, bioturbation, wave action, and disturbance by animals or people (Gregory 1998). Highly organic sediments, such as peat bogs and salt marshes, become anoxic within a few centimeters of the ground surface, significantly reducing oxygen flow and deterioration. Salinity levels influence what microorganisms are present at sites.

Deterioration of salt-waterlogged material

Salt-waterlogged objects deteriorate when allowed to air dry because the salt moves to the surface of the object, crystallizes and expands, cracks, and exfoliates the surface. Salt-waterlogged objects need to be desalinated by immersing them in freshwater to remove the salt. In low-fired pottery typical of many archaeological sites, once the salt has been removed, the pottery can be allowed to dry and the surface will be intact. Salt-waterlogged wood also needs to be desalinated by immersing the object or ship in water, and changing the water until it is fresh. Desalination time depends on the density and size of each object, but is generally a lengthy endeavor, taking months or years. Desalinated waterlogged wood will rapidly deteriorate if removed from water, resulting in changes to the wood structure, with internal cracks and collapse of cell walls, making microscopic species identification difficult or not possible, as well as shrinking and warping of the wooden object. Salt water deteriorates glass and metal artifacts.

Deterioration of waterlogged material returned to sites

Returning waterlogged finds to their origin site and covering them with sand bags, sediment, or plastic in order to recreate the anaerobic environment is a common solution for long-term preservation. If the reburial matrix is not anaerobic, decay of the waterlogged organic material occurs. Oak timbers (*Quercus virginiana*) stored for 50 years in freshwater had 4 percent loss in specific gravity, which translates as loss of strength of the wood (Winandy 1984).

Deterioration of waterlogged materials can be slowed by returning them to a matrix similar to their recovery conditions underwater. Pottery from the Paynes Creek Salt Works was cached in deep anaerobic silt underwater conditions after brief study and 3D imaging, with periodic checks indicating the low-fired pottery maintains its surface integrity.

Planning for excavation of waterlogged materials

A plan for study and disposition of waterlogged objects, buildings, and ships should be made prior to removal of waterlogged remains during survey or excavation. This includes consideration of short-term conservation for study as well as long-term conservation needs. Short-term conservation may be containerizing waterlogged objects in water for study, 3D imaging, and sampling. Long-term conservation may include returning objects to an underwater location or professional preservation by polymer (Smith 2003), freeze-drying (Walsh et al. 2014), PEG (Bruseth and Turner 2005), or refrigeration. Long-term conservation may include 3D digital imaging of the objects to maintain an accurate digital record, even if the original continues to deteriorate after professional preservation due to cracks or other conditions in antiquity. Long-term immersion in water will result in deterioration after a few years.

Deterioration of Wood

CATHERINE S. MALLINCKRODT

Virginia Museum of Fine Arts, USA

Introduction

Wooden artifacts and structures contain information about cultural and natural history at all levels, from the overall form to the microstructures. The receptivity of wood to deterioration is determined by the chemical, physical, and biological factors of the wood and of agents of deterioration in dynamic relationships. Knowledge of wood and the factors that influence and threaten it is essential to effective and ethical stewardship. The basic characteristics of wood and of the primary agents of deterioration and examples of common forms of ancient and historic preserved wood are presented here with the goal of providing a foundation for further study. There is a wealth of excellent resources available and I am in debt to those authors.

Wood

The two major taxonomic categories of trees are angiosperms referred to as hardwood and gymnosperms or softwoods. Angiosperms are broadleaf and produce flowers for pollination and are much larger and diverse taxa than gymnosperms that have needles and produce cones. Wood of both hardwoods and softwoods is the secondary xylem tissue that makes up approximately 70–93 percent of the biomass of a tree, with bast, bark, needles, and leaves making up the rest. Wood is primarily structural and provides transportation of water and nutrients. It grows inward from the cambium layer as phloem and bark grows outward. Cells are oriented longitudinally and radially, and wood structure is described using longitudinal, transverse, and tangential axes (Nilsson and Rowell 2012).

Wood cells differ seasonally, creating radial ring patterns which in temperate climates create annular rings. Older wood on the interior of the trunk ceases to function in transport and becomes denser and concentrated with extractives. This “heartwood” is usually more durable than the outer less dense “sapwood” and may be darker colored. Sapwood has a higher shrinkage rate when dried and is generally more vulnerable to microbes.

Wood is a biopolymer composed of three primary compounds—two polysaccharides, cellulose and hemicellulose, and the phenolic polymer lignin—and less than 10 percent non-structural compounds and extractives. These include pectin, tannins, terpenes, fatty acids, resins, and minerals. Pectin is present in cell walls, and extractives may impart color and odor and affect the durability of wood, but are not considered significant in evaluating agents of deterioration (Nilsson and Rowell 2012; Fanelli et al. 2008; Unger, Unger, and Schniewind 2001).

Cellulose comprises 40–45 percent of wood biomass. Parallel polysaccharide chains create microfibrils that group into fibrils that make wood fibers. Crystalline zones of microfibrils cause birefringence when observed microscopically (Fanelli et al. 2008). Hemicellulose, made of shorter polysaccharide chains, comprises approximately 35 percent of hardwoods and 20 percent of softwoods. Deterioration results from acid hydrolysis leading to decomposition, and specific microbial enzymes (Fanelli et al. 2008).

Lignins make up approximately 35 percent of softwoods and 25 percent of hardwoods. They are resistant to hydrolysis and sulfuric acid, but are broken down by oxidizing enzymes. Syringyl lignin in hardwoods is preferentially degraded by fungi (Unger et al. 2001; Berti, Palanti, and Pinzari 2008).

Wood cells have a primary outer lignin and hemicellulose wall, a three-layer secondary wall of cellulose and lignin, and around the lumen is a cellulose and hemicellulose layer. Wood cells are adhered together by pectin and lignins of the middle lamella (Berti et al. 2008). Specialized

architecture of wood tissue facilitates mechanical and transport functions. The chemistry of cellular features differs in vulnerability to chemical and microbial attack (Blanchette 2000).

Agents of deterioration

Risk is determined by the chemical, physical, and biological factors of the wood and of agents of deterioration in dynamic relationships. Pinna and Salvadori (2008) identify primary, secondary, and tertiary stages of bioreceptivity to describe how each phase creates the conditions for subsequent systems of deterioration. Increasingly refined analytical methods are being applied to determining mechanisms of deterioration and quantifying changes in wood.

Weathering

Discoloration, loss of surface cohesion and lifting fibers, warping, and cracking of weathering result from various impacts, including oxidation by ultraviolet light, acid hydrolysis by pollutants, and swelling and shrinkage and salt efflorescence cycles with atmospheric moisture (Unger et al. 2001; Catelli, Bănică, and Bănică 2016).

Fungi and bacteria

Microbial attack on wood in terrestrial climates is primarily from fungi and to a lesser extent bacteria. Submerged waterlogged wood in anaerobic environments is at risk from bacteria. Differences in microbial specialization, the chemistry and structures of the wood, and the environment will determine the type and nature of the degradation. Available moisture is a critical factor for microbe growth and a standard measure is the fiber saturation point—the amount of moisture present to saturate the cell wall plus some free water in the lumen (Unger et al. 2001; Blanchette 2000; Singh 2010).

Three categories of fungi are described by the visual characteristics at advanced stages of decay: white, brown, and soft rots. White and brown rot are caused primarily by basidiomycetes, of which there are thousands of species. White rot

targets lignin, causing blanching and deterioration of the middle lamella (Berti et al. 2008; Blanchette 2000). Detection may be delayed because wood retains its structure into later stages of deterioration. Brown rot attacks cellulose and hemicellulose and causes degradation of cell walls. Remaining dark lignin-rich wood cracks into a cubical pattern when dry. Loss of strength occurs early in the deterioration process. Brown rot, also called dry rot, is caused by *Serpula lacrymans*, which can remain active at relative humidity as low as 22 percent (Berti et al. 2008). Brown and white rot are optimized at water content between 40 and 80 percent of oven dry weight. Water content below 20 percent is recommended to protect wooden artifacts (Blanchette 2000).

Soft rot is primarily caused by ascomycetes fungi. These are slower acting than white or brown rot but tolerate higher moisture, alkaline pH, some preservatives, and low oxygen levels. Consequently, soft rot attacks waterlogged or damp wood. Two types of soft rot are distinguished. The first attacks carbohydrates but not lignin of hardwoods (angiosperms) and the middle lamella is retained or modified. Type two attacks polysaccharides of softwoods (gymnosperm), destroying the secondary wall but leaving lignin. Both reduce structural strength. Some basidiomycetes and ascomycetes cause only chromatic alterations but increase the hygroscopicity and therefore attract other microbial degradation (Unger et al. 2001; Berti et al. 2008).

Several groups of bacterial microbes that require high moisture content and are tolerant of low oxygen and anaerobic environments are active on waterlogged wood and wood in waterlogged soil. They break down cellulose and are associated with three types of microscopic deterioration: erosion, cavitation, and tunneling (Berti et al. 2008; Singh 2010; Reinprecht 2016).

Insects

Insect pests consume, excavate, and inhabit wood and are the primary animal agents of deterioration of terrestrial wood. The three most wood-damaging insects are hymenoptera, and two xylophageous or wood-eating beetles (Coleoptera) and termites (Isoptera). But there

are many insect species that damage wood, and attack may come from insects in other adjacent materials, such as dermestids that consume protein but infest previously decayed wood for pupation (Unger et al. 2001; Ilbach 2013).

Insect larval stages are the primary agents of destruction, though adults may also cause damage. Differences in the wood that is attacked and the type of damage varies with insect species and is determined by nutritional and reproductive needs, environmental conditions, whether the wood is a hard or softwood, and what species. Some species may require gut microbes to digest components of wood, have symbiotic relationships with fungi, or have restricted tolerance for temperature and moisture. Knowledge of these factors is critical to effective treatment; for example, heat treatment that denatures proteins required by house longhorn beetle (*Hylotrupes bajulus*) will not be effective on powderpost beetles (hycidae) that do not require protein (Unger et al. 2001; Reinprecht 2016). The discovery of insects, sawdust, or frass requires immediate attention to identify the insect, and determine and instigate the appropriate eradication method (Unger et al. 2001; Reinprecht 2016).

Other agents of deterioration

Wood-boring shipworms, the bivalve Teredinidae and the crustacean *Limnoria lignorum*, cause damage to submerged wood in marine environments, depending on the salinity and temperature of the water. Both attack hard and soft woods (Unger et al. 2001; Ilbach 2013). Many terrestrial animals cause damage and deterioration of wood through mechanical action and introduction of chemical agents as urine and food.

Archaeological and historic wood

Historic wooden heritage objects and archaeological wood have been preserved or partially preserved in desiccated, anaerobic, and frozen environments that constrained agents of deterioration (Nilsson and Rowell 2012; Matthiesen et al. 2014).

Desiccated wood

The best-preserved wooden artifacts have been found in arid conditions where the moisture content remained consistently below 20 percent, and therefore too low for sustained microbial attack, and the wood was protected from insect pests. Studies by Nilsson and Daniel identified microscopic degradation of the cellulose and weakening of microstructures, while the overall structure remained intact (Nilsson and Rowell 2012; Unger et al. 2001).

Waterlogged wood

Important waterlogged wooden heritage objects have been partially preserved in anaerobic marine and freshwater environments, and in saturated soil and silt. Fungal and microbial action is constrained, but cellulose and hemicellulose are eroded by hydrolysis, and anaerobic reducing bacteria attack lignin, reducing mass and structural strength (Florian 1990; Blanchette 2000). While submerged water replaces lost material and supports the structure, removal of the artifact causes catastrophic collapse unless the water is gradually replaced by a consolidant in complex conservation treatment.

Summary

Knowledge of structures and agents and mechanisms of deterioration is essential to the ethical and effective stewardship of wooden heritage objects. This overview is a foundation for research to determine conservation practices that will preserve the information latent within the structures and chemistry of wood.

Electron Microscopy in Conservation

SERGEY V. PRIKHODKO and IOANNA KAKOULLI

University of California, Los Angeles, USA

Brief history of microscopy

Conservation science addresses issues related to the protection and preservation of heritage materials, including works of art and architecture, and archaeological and historical artifacts. To a great extent, it relies on the evidence presented by the scientific tools employed in the analysis. Microscopy is among the most important techniques to address research needs. A microscope can be defined as a tool that transforms an object into an image, and as a result of such transformation we are able to see the smallest details of the object. *Resolution* is the smallest distance between two points on a specimen that can be observed as separate entities. The resolution of the human eye is generally accepted to be close to 0.1–0.2 mm and any tool that allows us to resolve smaller details can be classified as “a microscope.”

The simplest device which extends our ability to see details beyond eye resolution is a glass lens. Lenses are known to have been used by humans for thousands of years. The oldest known were used by ancient Egyptians and were made of natural crystals. The optical microscope, or “light microscope,” uses visible light and a system of glass lenses to magnify the object. These are the oldest and simplest of microscopes. Though under dispute whom to consider as the inventor of the light microscope, it is accepted that in the seventeenth century a Dutch engineer and craftsman, Antonie Van Leeuwenhoek, was the first to use a microscope as a scientific tool (Dobell 1958). He observed plants and small animals under the microscope and published his observations in scientific journals. Since then, light microscopy has significantly developed,

with improved resolution mostly by perfecting the quality of the glass lenses.

However, in the mid-nineteenth century, due to development of the wave theory of light, it was realized that the resolution of optical microscopy is limited by diffraction. Its physical limit is summarized by the Rayleigh criterion, which states that resolution is related to the *wavelength* of visible light: Resolution is higher (better) when the wavelength is shorter (Rayleigh 1879). Since the wavelength of visible light is roughly in the range 400–700 nm of the electromagnetic spectrum, it was recognized that the physical limit of light microscopy is somewhere around 200–300 nm. This triggered the search for a different type of microscopy that could surpass the resolution limit of light systems. Towards this goal, one of the greatest discoveries was made by the French physicist Louis de Broglie at the beginning of the twentieth century. His theory suggested that an electron has wave-like properties and its wavelength can be controlled by accelerating the voltage the electron travels through. This discovery revolutionized the field of microscopy, since it was recognized that the wavelength of an electron can be about five orders of magnitude shorter than the wavelength of visible light, allowing resolution capability far below the size of an individual atom.

One of the problems in using electrons instead of light in microscopy is that regular glass lenses cannot be used to control the electrons. However, the famous Lorentz equation addressed this concern, showing that electric or magnetic fields could be used instead. Thus, the idea of using magnetic lenses to focus high-energy beams of electrons did not take long to put into practice. In 1931, two German physicists and engineers, Ernst Ruska and Max Knoll, invented the first *transmission electron microscope* (TEM). The development of the *scanning electron microscope* (SEM) in 1942 by US engineer Vladimir Zworykin was related to the invention of the TV signal processing, which is principally different from the optical signal used in TEM. A fundamental discovery made by British chemist Henry Moseley in 1913 showed that the energy of emitted characteristic

X-ray radiation produced by a specimen exposed to a high-energy electron beam is a function of the atomic number of the emitting element. This discovery led to the technique of X-ray spectrochemical analysis, by which elements present in a specimen could be identified by their characteristic X-ray energies. The first electron microscope suitable for elemental analysis was built in 1949 by Raimond Castaing and André Guinier.

Basic principles of electron microscopy

Electron microscopy (EM) applies a high-energy electron beam. When electrons interact with the sample they get scattered and are capable of *ionizing* the matter's atom, that is, of removing the inner-shell electron from the attractive field of the nucleus. As a consequence of electron scattering, the specimen produces different signals in EM. These include: *secondary electrons* (SE); *backscattered electrons* (BSE); *characteristic X-rays*; *Auger electrons*; *cathodoluminescence* (CL); specimen current; and Bremsstrahlung X-ray. All these signals are generated simultaneously, but require specialized detectors. SE signal is generated by the electrons that are initially part of the specimen but got knocked out as a result of scattering. BSE results from multiple elastic scatterings of the primary electrons by the specimen. Energies of SE and BSE are not specific for the specimen's atoms, and signals are only used for imaging purposes. Signals are defined by their energies: SE are bound to the energy range of 0–50 eV, and BSE are 50 eV and up to E_0 , where E_0 is the accelerating voltage EM uses. Due to the big difference in their energies these signals can give distinctively different types of images. Characteristic X-rays are produced by the atom of the specimen as a result of bringing the atom to the ground state after one of its inner-shell electrons got knocked from its orbit by the high-energy beam electron. Auger electrons emission is an alternative (to X-ray) way of relaxation of a specimen's atom: The atom can emit its outer-shell electron (Auger) instead of the characteristic X-ray photon.

Characteristic X-ray and Auger electron signals carry very specific energies that represent the scattering atom of the specimen, and that is why

they are primarily used for elemental chemical analysis. Characteristic X-ray and Auger electron emission are related. The probability of Auger electron emission is higher for light elements contrary to X-ray emission, and vice versa for heavy elements. This makes Auger spectroscopy one of the most powerful techniques for the detection of light elements, and X-ray signal techniques for medium and heavy elements. There are two different methods in EM that make use of the characteristic X-ray signal: energy-dispersive spectroscopy (EDS) and wavelength-dispersive spectroscopy (WDS). These are different in terms of the X-ray signal detection and processing and provide different accuracy and sensitivity for element detection (Goldstein et al. 1992). CL is a signal of light produced by the specimen as a result of its bombardment by high-energy beam electrons. The wavelength of emitted light depends on the band-gap size of the material, and its measurement can address band-gap value-related problems in materials. The specimen's current signal distinguishes areas on the specimen with different conductivity.

Except for the Bremsstrahlung X-ray (background on X-ray spectra), all of the signals have useful applications in different types of EM. TEM mostly uses nonscattered (transmitted) and elastically scattered (diffracted) electrons. SEM mostly uses SE, BSE, and characteristic X-ray signals. All other signals, including Auger electrons and CL, require a more specialized system design, but the instruments which use these signals also belong to the class of EMs where the high-energy electron beam is used as a primary source.

EMs are highly regarded scientific tools since they can provide data on topography and morphology of the specimen at resolutions much higher than light microscopes: commonly, a few nanometers in SEM and a few angstroms (or better) in TEM. EMs can also provide information on the crystal structure and elemental composition of the specimen, not achievable with the light microscope. SEM can be considered as a scientific tool suitable to image the external structure of a specimen, and TEM, the internal structure.

Although TEM and SEM are both electron microscopes, they operate by different principles. Their major difference is based on the type of image formation they use and it determines the way we magnify the object, and calculate the

resolution and depth of field, and some other important characteristics. TEM uses lenses to magnify an object. This type of image formation is called *optical*. In this respect, TEM is very similar to the light microscope; the only difference is that it uses magnetic lenses instead of glass lenses. Furthermore, it requires the specimen to be transparent for the electrons, and therefore samples need to be very thin (~100 nm). The image contrast is formed due to the difference in electron scattering by different areas on the specimen. The areas on the sample that scatter more strongly will appear darker in the image. This mechanism is called *mass-thickness contrast* and it is the most commonly used contrast mechanism in TEM.

Two other contrast mechanisms exist in TEM: diffraction contrast and phase contrast. These are more important particularly for the crystalline materials and when TEM operates at very high magnifications. TEM is the perfect tool when high resolution is required, and it can solve different problems related to crystallography since it allows collection and study of electron diffraction routinely. TEMs can be equipped with EDS systems for chemical analysis. However, TEM requires microsamples (normally 3-mm disks), which can pose challenges in the analysis of archaeological materials, as sampling could be a limiting factor.

SEM utilizes a *scanning* type of image formation. The image is formed by individual pixels (picture elements), which are formed at different time intervals. In an electron scanning image, a high-energy electron beam moves across a small rectangular area on the specimen with changing x and y coordinates on the specimen, creating a raster. Each pixel of the object generates all varieties of signals, which can be collected by the specialized detectors. Collected signal modulates the intensity of the pixel on the cathode ray tube or a computer monitor. The x, y position of the pixel on the monitor and on the specimen's raster is correlated so that the beam motion over the sample and the pixel's reading on the monitor are synchronized. Due to the high frequency of the scanning (50 frames per second in TV mode), the image appears to the human eye as formed instantly. It becomes evident that the scanning type of image does not need lenses to magnify the object. Magnification in SEM is determined by the ratio between the size of the monitor used and the raster applied on the specimen. However,

SEM uses magnetic lenses to focus the electron beam (demagnify its size) on the sample, forming a small-size probe. Probe size determines the spatial resolution of SEM.

One of the most important characteristics of the scanning type of image formation is the very high *depth of field* compared to the optical image, which is often valued—even higher than a good spatial resolution. As a result, the sample can be studied in SEM without having been polished flat. The most important signals which are used for imaging in SEM are SE and BSE. Both signals' intensities are directly related to the local tilt of the specimen toward the electron beam: The higher the tilt, the stronger the yield of both SE and BSE. This is a major mechanism for *topographic contrast* that can be formed with both signals. In addition, the yield of BSE depends on the average atomic number (Z) of the area on the specimen analyzed and it is stronger when Z is higher. This makes it possible to observe *compositional contrast* with BSE. The coupling of EDS or WDS with SEM enables simultaneous elemental analysis of the sample. It is important to note that due to the different principles these two techniques use, the limit of detection and the energy resolution (ability to distinguish between elements with very similar energies) are very distinct. In optimal experimental settings (flat polished surface of the specimen, adequate beam current and X-ray signal) the limit of detection of EDS is about 0.1 wt%, whereas in WDS it is about 0.01 wt%. Due to its excellent energy resolution, WDS is capable of distinguishing signals from all elements, whereas EDS very often is incapable of doing this. For example, Pb, Mo, and S (respective M, L, and K photon emissions) are nondistinguishable with EDS. In SEM the distribution of the chemical elements across the sample surface can be mapped and correlated to the electron topographic or compositional contrast images. Spatial resolution of EDS in SEM is generally accepted as approximately 1 μm , whereas in TEM it is about two to three orders of magnitude better. Currently, SEMs are routinely equipped with an *electron backscatter diffraction detector* (EBSD), which allows the measuring of crystallinity of the specimen within a few tens of nanometers.

One of the most important advancements in SEM is the use of differential pumping systems

and a series of pressure-limiting apertures which allows SEM to operate at variable pressure (VP) (50–300 Pa) or environmental (E) pressure (up to 900 Pa), while the electron gun compartment is at very low pressure (10^{-5} Pa and better). These SEMs allow charge neutralization on the specimen and do not require the specimen to be conductive. They also allow for dynamic studies by changing the environmental conditions in the chamber (Stulik and Doehne 1991). Large SEM chambers also enable the study of big specimens or entire objects (70 cm in diameter and 300 kg in weight) (Mayer et al. 2007). Finally, recent progress in electron optics and electron source (field emission guns) design makes modern SEM an extremely versatile and powerful tool capable of studying heritage objects nondestructively and often noninvasively.

New developments in integrating different technologies led to the revolutionary coupling of a VP-SEM with Raman spectromicroscopy (μ RS). The coupling of the VP-SEM with EDS and μ RS unites three well-established technologies in a novel interfaced system. It takes full advantage of the high spatial resolution offered by the VP-SEM for nondestructive in-situ submicron morphological and topographic mapping, and the atomic and molecular microprobing of the EDS and μ RS for simultaneous spatially resolved elemental composition and chemical speciation of materials.

EM applications in conservation

Scientific studies to understand ancient technology and materials' degradation are very important components in heritage conservation. Understanding the make-up of objects and assessing degradation is vital to inform conservation decisions and treatments. By combining the imaging and analytical capabilities of the different detectors (SE, BSE, and EDS), crucial information can be obtained from microscopic specimens for answering important questions related to an artistic technique or the state of preservation of an artifact (Barabe 2003; Ciliberto and Spoto 2000). As many heritage materials are nonconductive (or could dehydrate or outgas in high vacuum), VP-SEMs provide a suitable

alternative to high-vacuum systems. This technology enables the analysis of small specimens without modification to their chemistry and structure (Prikhodko et al. 2007).

E-SEMs can further enable dynamic studies of materials to monitor phase transformations and weathering in real time, by modifying the environmental parameters in the SEM chamber. This was demonstrated by dynamic experiments on stone preservation affected by salts (Baker, Uwins, and Mackinnon 1993; Doehne 2006). Another preservation-related challenge often encountered by conservation scientists that could be facilitated using E-SEM is finding the optimum range of relative humidity and temperature for the long-term preservation of artifacts (Doehne and Baken 2006).

The coupling of VP-SEM with EDS and μ RS has offered new capabilities for noninvasive and minimally invasive analysis of heritage materials. Using a VP-SEM-EDS- μ RS system, questions requiring topographical and compositional contrast, and elemental and chemical composition can be answered without having to move the specimen/object and without the need to coat the samples (Prikhodko et al. 2015).

It is important to emphasize that EM provides nondestructive analysis, as it does not consume the sample to yield results. In this respect it can complement some other traditional methods used in conservation, for instance polarized light microscopy, portable XRF, and Raman and infrared spectroscopy. An advantage is that the same samples analyzed using SEM can be further analyzed by some other common techniques. This helps maximize the information obtained from the study of objects to inform conservation decisions.

Grouting in Conservation

BERIL BIÇER-ŞİMŞİR and LESLIE RAINER

Getty Conservation Institute, USA

Grouting is an intervention method intended to restore the continuity of elements, such as walls, plasters (see CONSERVATION OF POLYCHROME NATURAL AND ARCHITECTURAL SURFACES), wall paintings, mosaics (see CONSERVATION OF MOSAICS) (see Figure 1a), and stone ornaments (see CONSERVATION OF STONE AND PETROGLYPHS), in the context of archeological sites, historic buildings, and monuments, by readhering detached areas or elements and filling voids and cracks that are inaccessible or difficult to access from the surface. While sometimes used interchangeably in the literature, it is important to emphasize that, as an intervention method, grouting differs from consolidation (see MINERAL INORGANIC TREATMENTS and POLYMERS IN CONSERVATION), which intends to reestablish cohesion of materials (stone, bricks, mortars, etc.) that have lost their binder.

Grouting applications for conservation can be grouped under structural and nonstructural grouting based on their function. Structural grouting aims to fill cracks and voids within the wall core or separation between the leafs of a masonry wall. Structural grouting is suitable when cracks and voids in the wall could cause structural instability and problems of water infiltration. Nonstructural grouting addresses voids and cracks in architectural surfaces. It aims to reestablish adhesion between delaminated layers of stone, plasters, wall paintings, and mosaics, or between these layers and the substrate.

Methodology

A systematic and well-defined condition assessment is crucial to identify conservation issues, and to determine if grouting is the most suitable intervention method for the specific case.

In some cases pinning with dowels, anchoring, or tie-bars may be used, and these techniques have been used in the past to reestablish the connection between wall leafs or between layers of architectural surfaces or architectural surfaces and substrate. Surface delamination can sometimes be repaired using a compatible mortar fill. It should be noted that grouting is an irreversible intervention, and retreatability can be challenging, particularly if a previous grouting intervention prevents the entrance of new grout. Additionally, grouting involves drilling holes on the surface to access voids, which leads to permanent damage of the historic fabric. Most of the time existing surface cracks can be used as injection points to minimize the damage, especially for decorated surfaces where the surface is of great value.

The focus of the condition assessment is to identify the condition of existing materials (both original materials and repairs), understand the past and current exposure conditions, document and map deterioration (see DETERIORATION) symptoms, and understand the related deterioration mechanisms, combined with material analysis to characterize original materials (e.g., plaster, stone, brick).

A variety of nondestructive, minimally destructive, or in some cases destructive diagnostic tools can be used for the condition survey in the field and laboratory. To detect delaminations and voids behind the surface, techniques include percussive tapping, infrared thermography (see THERMOGRAPHY), endoscopy or fiber optic probe, laser speckle interferometry (electronic speckle pattern interferometry (ESPI) or TV-holography) (Hinsch et al. 2009), sonic tomography (Silva et al. 2014), and ground-penetrating radar (see GROUND-PENETRATING RADAR). Additionally, a number of analytical laboratory tests can be performed on collected samples (core samples (see CORING), powder, chips, etc.) to study the chemical, physical, and mechanical characteristics of the materials to be treated and to identify existing deterioration mechanisms. These include

elemental analysis (e.g., X-ray fluorescence [XRF], see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) and scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDS), compositional analysis (e.g., X-ray diffraction [XRD], see XRD AND MATERIALS ANALYSIS), thermogravimetric analysis–mass spectrometry (see MASS SPECTROMETRY (MS)), and petrography (see PETROGRAPHY AND CERAMICS), wet chemical analysis, sieve analysis, salt analysis (e.g., ion chromatography [IC], see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS), porosity, water absorption, vapor permeability, and strength measurements (Silva et al. 2014).

Based on the information collected during the condition assessment, the need for grouting, the desired properties of the grout, and the development or selection of a grout that will be compatible with the original materials for the specific case can be determined. These decisions should be made by an experienced interdisciplinary team including conservators, conservation scientists, conservation architects, and structural engineers. Since grouting is an irreversible intervention, the selection or development of an appropriate grout is crucial for the success of the intervention and to avoid the need for frequent repeated interventions.

Selection or design of a grout

A grout is a bulked fluid material including one or more binders (see CEMENTS, MORTARS, BINDERS), fillers (ultrafine or fine aggregate), liquid, and generally admixtures to control its fluidity. Due to compatibility concerns, water-based mineral grouts are commonly used and the use of polymer-based or other solvent-based (epoxy and polyester resin) grouts are not recommended. In the conservation field, both custom mixed and commercial proprietary grouts are used. With the general acceptance of preserving architectural surfaces in their original context, a number of commercial grouts have been developed for various uses (e.g., lightweight grouts, grouts for frescoes, etc.) since the 1980s. Custom-mixed grouts are typically designed for specific use on a case-by-case basis (Ferragni et al. 1984).

The required properties of a grout should be selected after considering the deterioration issues identified in the field (e.g., deep voids requiring low shrinkage grouts; voids in vaults and ceilings requiring lightweight grouts; fine cracks and thin delaminations requiring very fluid grouts) and the function of grout (structural or nonstructural).

In general, grouts should be compatible with the original materials (substrate and plasters). They should be fluid enough to be injected with no clogging and have minimal separation of components. The volume shrinkage of a grout (from wet paste to hardened solid) should be minimal. Additionally, the concentration of soluble salts in the grout should be as low as possible. The hydric transport properties (i.e., capillary water absorption and water vapor permeability) of the cured injection grout should be similar to that of the original material, and the cured grout should not create a vapor barrier. Following conservation principles, the mechanical properties (i.e., compressive, shear, or tensile strength, modulus of elasticity) of the cured injection grout should be similar to, but less than, the original plaster and substrate to avoid any damage to the original material under existing exposure conditions. Grouts should provide an adequate bond, and the bond strength at the interfaces should be similar to but less than the strength of the original materials. For cases where the aim of grouting is the strengthening or retrofitting of masonry structures, the effectiveness of grouting to fulfill this aim without developing extreme strength (mechanical or bond) and rigidity should be demonstrated. Finally, injected grouts should be sufficiently durable.

The properties of grouts that can be measured in the laboratory include expansion and bleeding, injectability (see Figure 1b), drying shrinkage, splitting tensile strength, soluble salt content, coefficient of capillary water absorption, water vapor permeability, wet and dry densities, shear or tensile bond strength, and resistance to salts or freeze-thaw. Since grouting has become a commonly used intervention method in conservation, research has focused on the development of appropriate testing methods and the development of a comprehensive and systematic evaluation of injection grouts both in the laboratory and field (Biçer-Şimşir and Rainer 2013; Jorne, Henriques, and Baltazar 2015).

Once one or more candidate grouts have been identified, they should be tested in the field prior to implementation. It is important to note that conditions in the field can differ from laboratory conditions, and may affect the performance of the grout. Following field trials, complications with the grouting process should be identified

and necessary precautions should be taken. If the performance of the grout is not satisfactory, modifications to custom-mixed grouts can be made and different commercial grouts can be tested.

Before grouting

Preparation of the area (wall, ceiling, vault, floor, etc.) to be grouted is critical to a successful grouting intervention. If necessary other interventions such as consolidation, desalination, or mortar repairs should be carried out before grouting. Debris, which has accumulated in voids, should be thoroughly cleaned out. For architectural surfaces, this may be done by aspiration using mini-vacuum attachments (e.g., computer vacuum attachments), air bulbs, and other small tools to empty cavities of debris. Often a hole must be made to access and empty debris. Water or preferably a water and alcohol (50:50) mixture can also be used to flush the cavity. Similarly, interior surfaces can be prewetted to facilitate passage of the injection grout through interior networks prior to grouting, to ensure adequate adhesion of the grout, and to avoid rapid drying. When liquids are used to flush or prewet, caution should be taken not to inject excess water in the void behind the surface, as it can dilute the grout mixture and modify its properties. The use of water to flush or prewet can also mobilize existing salts and lead to surface or subsurface efflorescence. Plant growth should be removed prior to grouting, as root systems might also prevent the grout from flowing properly. For structural grouting, a grid of injection ports can be prepared. In some instances, air holes may be drilled to facilitate passage of the grout. However, on most wall paintings, this is not advised, and typically, preexisting holes, cracks, or losses are used as injection ports when possible. For structural grouting or filling of large voids, a grid of application holes is drilled, but this is clearly not desirable for wall paintings' conservation. Holes through which the grout could leak, should be sealed to prevent grout from dripping onto the surface; fine cracks may be faced, and if necessary, the edges of the area to be treated can be sealed with materials such as plasticine, cyclododecane, or a mortar used for fills.

Grouting

Once one or more grouting areas have been prepared, the grout mixture is prepared and introduced. The most common grouting methods are gravity and pressure grouting. Application of vacuum grouting in conservation is very limited largely due to the need for extensive preparation (vacuuming out air and water) and issues of incompatibility with the use of low-viscosity resins. It should be kept in mind that grouting is a challenging procedure and should be undertaken by only experienced conservators and conservation professionals.

For nonstructural grouting, the technique utilized to introduce grout into the void depends upon the size, accessibility, and alignment of the void. If the void can be accessed from the top, then the grout can be introduced at the upper edge and allowed to flow down inside the void, using gravity grouting, which can also be used for floor mosaics. Otherwise, grout is usually injected by syringe with a cannula of appropriate size (Figure 1c). For especially large voids, transfusion tubing can also be used.

While gravity grouting is simpler in terms of equipment and application requirements, low-pressure pumping is usually the most appropriate method for structural grouting.

Both structural and nonstructural grouting starts at the base of the wall or void when possible. In the case of particularly large cavities, the grout should be applied in stages or lifts, to give each grout application sufficient time to lose water and become fairly dry and hard.

Frequently, and particularly in the case of fragile architectural surfaces and vaults, it may be necessary to hold the plaster, wall painting, or mosaic in place by the use of supports while grouting is being carried out and during setting. Applying pressure to the grouted area can, in some cases, also realign a deformed plaster and provide better contact and adhesion of the grout to the substrate and plaster layers.

During grouting, work should be monitored. The penetration of grouting can be monitored by nondestructive methods such as thermography and laser speckle interferometry as described above.

After grouting

Following grouting, the surface should be checked to ensure that no grout remains on the surface. Grout may flow and reappear on the surface in unexpected places and excess grout may discolor the surfaces on which it is deposited if it is not removed in a timely fashion.

Periodic post-treatment monitoring, using nondestructive diagnostic tools should be carried out to ensure the durability of the treatment over time and to identify new cracks, voids, and delaminations. An evaluation of the wall, plaster, wall painting or mosaic should also be carried out after a natural disaster such as seismic activity or any other event that could cause damage.

Inpainting

ANTONIO IACCARINO IDELSON

Conservator, Equilibrarte, Italy

LEONARDO SEVERINI

Independent Conservator, Italy

The noun *inpainting* is a prepositional compound with “in”: in + painting, that is, “painting inside.” It seems to have appeared in the conservation literature of the United States in 1935 (Metzger, Maines, and Dunn 2011), when it was proposed by G. L. Stout and described as “placement of new paint in the lacunae of the old film” (Stout 1935). Buck and Stout (1940) offered a definition of inpainting as “compensation of losses with no new paint put over that which is old and original,” thus avoiding arbitrary intervention, and distinguished it from overpainting which goes “beyond mere compensation in the area of loss.” This approach characterizes the modern profession of “conservator,” which was then being established in Europe and in the United States; conservators were replacing the outdated approach of the restorers of the previous generations, whose overpainting often obliterated and modified original parts of the painting. “Retouching,” a more widespread term, though older and less specific, describes the artist’s action of perfecting his or her painting with touches of color. In the United States more than in Europe, the term “inpainting” is preferred to retouching, because it speaks to the aim of modern conservation practice to introduce new ethical standards and techniques.

Compensation for losses has been a crucial point in all theoretical and ethical approaches to conservation (Hill Stoner and Rushfield 2012). The conservator may reduce the visual disruption caused by the loss or alteration of the original paint layers by adding color, either through mimetic (imitative) retouching or in a differentiated way. Being among the conclusive steps of a conservation treatment, inpainting is also the one that acts as mediator in the relationship

with the public and facilitates understanding of the painting. It is therefore not surprising that inpainting is often identified with the entire process, especially since to restore literally means to reinstate the missing parts of an object.

Pietro Edwards, chief restorer for the public paintings in Venice in the late eighteenth century, recommended the least possible amount of integration, mostly within the losses, and with varnish-bound colors that could be removed with no damage to the original painting. The instructions in his writings reveal a deep understanding of the realities of the process—an understanding that derives from his personal involvement in the treatment of paintings (Tranquilli 1996).

Imitative and interpretative overpainting prevailed until the beginning of the twentieth century, when a more rational and respectful approach was reinstated in the field of painting conservation. The International Conference for the Study of Scientific Methods for the Examination and Preservation of Works of Art, held in Rome in 1930, is considered to have been a seminal event for the establishment of the modern discipline of conservation (International Museums Office 1997). The subject of retouching held a central place in that discussion, identifying the distinction between the modern imitative techniques and the traditional “deceptive” ones. The importance was made clear of limiting the intervention to the areas of loss, working with reversible materials, and ensuring the recognition of inpainted areas through photographic documentation. At the Rome Conference Helmut Ruhemann (1968) proposed to work on differentiated retouching; but later on he went back to mimetic reintegration, as no method seemed satisfying.

Imitative inpainting is based on a long-standing tradition and its principles and development are empirical rather than based on philosophical reasoning. Indeed, imitative techniques are those most often used at an international level. Prioritizing the unified appreciation of the painting, they allow for the important element of the conservator’s subjectivity when facing the great variety of damages sustained by the original paint layer.

The need for shared and structured principles has motivated the redaction of guidelines for ethics. In the Code of Ethics and Guidelines for Practice issued by the American Institute for Conservation, we read (https://www.nps.gov/training/tel/Guides/HPS1022_AIC_Code_of_Ethics.pdf):

Any intervention to compensate for loss should be documented in treatment records and reports and should be detectable by common examination methods. Such compensation should be reversible and should not falsely modify the known aesthetic, conceptual, and physical characteristics of the cultural property, especially by removing or obscuring original material. (23: Compensation for Loss)

The concept of “authenticity” is connected to that of “autography” and even to that of “truth”—notions that have always aroused respect and reverence. At the core of the debate in the history of restoration and conservation, the conflict between authenticity and unified appreciation of the artwork has seen solutions ranging from stylistic reinterpretation to archaeological presentation of autograph fragments of paint layers. Nevertheless, the definition of authenticity has changed over the centuries, moving away from the “competitive” approach of the Renaissance and baroque periods, when older works were reshaped so as to acquire new value instead of losing it. During the Enlightenment, the progressive application of the scientific method to all the fields of culture directed new attention to the original materials, as demonstrated in the work of Pietro Edwards. A contemporary definition of authenticity is expressed in the 1994 Nara Declaration on Authenticity (available on the UNESCO website, at <https://www.icomos.org/en/about-icomos/179-articles-en-francais/ressources/charters-and-standards/386-the-nara-document-on-authenticity-1994>). According to the Nara statement, the conservation of cultural heritage is rooted in the values attributed to heritage by the stakeholders. Values, and authenticity more than others, depend on the degree to which the information sources related to them are credible or truthful. Such evaluations may differ from culture to culture, and even within the same culture. It is thus not possible to

base judgments of value and authenticity on fixed criteria.

The Italian approach to the problem of authenticity versus the subjectivity of the conservator is grounded in the comprehensive theory of conservation developed by the art historian Cesare Brandi between the 1940s and the 1960s as he aimed to guide the treatment of losses through a philological and critical approach (Brandi [1963] 2005). His best known concept of a “theory of restoration” (*teoria del restauro*, Brandi [1963] 2005) is that of the recognizable integration of losses achieved through the *tratteggio verticale* (“vertical hatching”). Similar hatching techniques, such as the *selezione cromatica* (“chromatic selection”) and the *astrazione cromatica* (“chromatic abstraction”), were proposed in Florence by Umberto Baldini in the 1970s (Casazza 1981). The *teoria del restauro* was developed within the philosophical discipline of aesthetics and had important contributions from Gestalt psychology, namely regarding the ability of the human brain to visually integrate specific kinds of losses and to differentiate between the respective roles of image and background—which proved to be particularly useful for works of art built with a stratigraphic sequence of distinct layers. These considerations resulted in a reduction of the amount of integration of losses that was necessary in order to establish a correct balance between the aesthetic and the historical cases. The typological differentiation of losses according to their position in the stratigraphy—whether they affected intermediary layers of paint or only the uppermost pictorial surface—was a key element.

The choice that was considered to be the most respectful one was to treat the loss chromatically, in order to have it recede to a lower layer in the stratigraphy, thus reducing its perception by assimilating it into the background. A superficial paint loss can be assigned the perceptual value of an area where the preparatory layers, made visible by the lacuna, are easily interpreted as having that value. These areas looked clean and consistent and seemed to belong recognizably to a lower layer (with respect to color, surface texture, and level); thus their disruption of the readability of the painting was considerably reduced. This emphasized the original, surviving paint surface and allowed it to be more greatly valued. This

“level switch” is as effective on paintings with a precise and constant stratigraphy (e.g., most easel and mural paintings) as it is on a variety of other artifacts (e.g., painted wooden sculptures and ceramics). Within the *teoria del restauro*, this technique—which, strictly speaking, is not inpainting but a different method for the treatment of losses—is always deemed preferable, though carefully weighed against the aesthetic limitations it imposes.

For losses in which the reconstruction of the image is deemed necessary and possible without arbitrary interpretations, the *teoria del restauro* proposes the use of a technique of inpainting that is recognizable only through close examination: *tratteggio*. Thin vertical strokes of highly contrasting colors, traced in very close proximity to one another on the white base of the gesso fills, reconstitute the image with sufficient accuracy to guarantee the complete illusion of the absence of a lacuna.

The broader influence of the *teoria del restauro* has been limited by several factors. Primary among these is its limited dissemination outside the Romance-speaking world, as it was not translated before the 1990s. Although many European countries have shared Brandi's approach and methods, limitations arise, also in Italy, from considerations about the supposed need for a trained eye in the observer and about the higher costs of a longer process of loss compensation.

Despite the fact that the *teoria del restauro* proposes a structured formula for the reintegration of losses (Mora, Sbordoni-Mora, and Philippot [1977] 1984), it also leaves margins for the necessary subjectivity of the ultimate choice among the various possibilities that each problem presented by the painting allows. Although both the mimetic and the recognizable inpainting methods are viable, for each specific problem, the process that leads to a solution can only be guided by gradual comprehension, which requires lateral thinking and is based on trial and error.

More recently, by an interesting coincidence, the term *inpainting* has also been adopted in software language, in the reconstruction of missing parts in digital photographs and videos. Algorithms that extrapolate information from the surviving areas around these missing parts are used to reconstruct them according to the criterion of the minimum visual interference.

These semiautomated methods are structured according to the mechanisms of human visual perception described by Gestalt psychologists (among others) and are proposed for the treatment of missing parts in digital photographs of old paintings (Schönlieb 2015). Such techniques will soon become available for use in combination with digital printing methods, which have recently been successfully used for transferring printed images in the losses of wall paintings in order to assist and reduce manual inpainting. Prefabricated elements introduced in the integration work carried out by the conservator may add a new level of efficiency to the process and make the integration of large losses more cost-effective.

When heritage has been damaged by war or by natural disasters, complete reconstructions are often asked for in order to preserve its symbolic meaning in terms of collective identity. The decision process ought to be rooted in the clear understanding of the requirements of the stakeholders, which need to be harmonized with the physical condition and needs of the artifact. In a time of frequent war conflicts and rapid technological developments, conservators need to exert special awareness.

In conclusion, if inpainting has been the object of reflections and successful prescriptions, the part of it that is performed on the original paint has been, and still is, considered risky, even though it is now always performed with reversible paints. As a matter of fact, inpainting involves the risk of regressing to the practices of overpainting, from which the modern profession has moved away with determination.

Inpainting is defined alongside its process and intrinsically connected with its action. For this reason most of the responsibility stays with the “critical action” of the conservator, which in turn depends on his/her sensitivity while facing constantly changing challenges. The maturity of the profession, nowadays guaranteed by the availability of highly specialized conservators and by their close interaction with the other professions, allows relying on a higher level of awareness at an international level. Nevertheless, most of the theoretical frameworks of inpainting have been produced by professionals who do not have direct responsibility (Muñoz Viñas 2005) for the operations performed on the artifact.

The new technological frontiers and the aesthetic demands of a world dominated by perfect images in an “age of tourism” raise new challenges for conservation ethics. In a global society that seems to be progressively less willing to accept the presence of imperfections in artifacts with a shared value, a bigger effort to discuss and bridge between professionals and the other stakeholders seems to be more urgent by the day.

Laser Cleaning

PARASKEVI POULI

Institute of Electronic Structure and Laser, Foundation for Research and Technology-Hellas (IESL-FORTH), Greece

Lasers have been introduced in the cultural heritage (CH) conservation science during the last 25 years and have progressively established themselves as unique tools for approaching complex diagnostic and restoration problems efficiently (Cooper 1998; Fotakis et al. 2006). The high intensity of a laser beam, its monochromaticity (the ability to be emitted in a single or in a narrow band of wavelengths), its directionality, and its coherence are unique properties that enable spatial confinement, selectivity, remote action, immediate control, and feedback and thus made possible the broad use of lasers for analytical and cleaning purposes in the CH field.

Laser–material interaction is a multiparametric process influenced by several parameters, including the physicochemical properties of the material and the operational characteristics of the laser system. The former refers to properties inherent of the material and thus particularly influential for its behavior upon laser irradiation, as for example the absorption coefficient (α), thermal conductivity (k), heat capacity (C) and molecular weight (MW). On the other hand, the laser characteristics—that is, its wavelength (λ), intensity, fluence (i.e., energy per unit area: $F = E/S$), pulse duration (τ_L), repetition rate, and beam quality—can be carefully chosen and thus the optimum laser–material interaction can be defined and selected (Georgiou, Anglos, and Fotakis 2008).

The fine-tuning of these parameters regulates and controls how much of the incident laser radiation will be absorbed, transmitted, and scattered by the irradiated material, and therefore affects specific applications (e.g., imaging, analysis, modification, and processing/removal of materials). Moreover, the relative percentage of the radiation absorbed by the substrate is decisive for

subsequent phenomena (thermal/photochemical modifications, plasma formation) or for the reemission of fluorescence and phosphorescence, and hence favors analytical, diagnostic, or material processing applications.

Along these lines, a laser beam focused on a material can reveal valuable information on its chemical composition on the basis of spectroscopic analysis (Nevin, Spoto, and Anglos 2012), while, conversely, when the laser beam is shined onto a wider area of the object, laser interferometry enables the detection of hidden alterations and structural defects (Tornari, Tsiranidou, and Bernikola 2012). In case of favorable conditions, lasers may, on the principle of laser ablation, induce progressive and controlled removal of layers. Laser ablation relies on the synergy of thermal, photochemical, and photomechanical effects and is a quite complex process. Upon optimization—that is, for a laser beam of intense energy density and short pulse duration, which is emitted at a wavelength that is strongly absorbed by the material—laser ablation may result in controllable material removal, with negligible thermal load or damage to the remaining material. As a result, in a variety of CH conservation challenges, altered overlayers and unwanted accumulations can be selectively removed, to reveal the original surface.

The most crucial issue for a successful cleaning intervention is the revealing of the original surface without any damage, and therefore spatial confinement and control of the laser ablation effects is important. “Self-limiting” mechanisms in laser ablation are responsible for many successful cleaning interventions, but this condition does not apply to all cleaning challenges; thus extensive studies have been carried out with the aim of proving and establishing laser cleaning.

Although the use of lasers to eliminate material in industrial (processing and microelectronics) and medical (eye/dental surgery) applications is well established and extensively studied both at the theoretical level and in practice, further studies are necessary for a smooth transition to the CH field. These studies refer to the systematic

investigation and elucidation of the associated ablation mechanisms, the assessment of potential chemical and thermal modifications induced in the remaining material (Georgiou, Anglos, and Fotakis 2008), and the understanding of side effects (Pouli et al. 2012). During the past 25 years operative laser parameters were confidently optimized and cleaning methodologies for each conservation challenge were developed and fine-tuned. Thus nowadays, having acquired this experience as well as some critical evaluation by comparison to conventional cleaning practices, laser cleaning is established and conservators and restorers have the choice of using highly sophisticated laser-cleaning systems. Furthermore, technological improvements allowed the transfer of laser technology on site and several successful laser-cleaning applications *in situ* have been reported, for example the removal of black pollution accumulations from St. Stephen's Cathedral, the Amiens Cathedral, and the sculptures of the Athenian Acropolis (Pouli et al. 2016), the cleaning of the gilded decorations on Florence monuments (Siano and Salimbeni 2001), and the removal of acrylic overpaints from the "black" oil paintings by Ad Reinhardt (Melessanaki et al. 2006).

A key parameter in laser cleaning is the absorptivity (at the operative laser wavelength) of the involved materials. Absorptivity determines the ablation threshold (the critical fluence value designating initiation of the material removal process) and the thickness of the removed material. Furthermore, it influences the extent of any thermal and chemical effects that may be induced in the remaining material. In fact, a highly absorbed laser beam will result in effective material removal (in thin layers and low ablation thresholds), with minimal alterations to the remaining surface. Obviously, the optimum operative laser fluences must lie above the ablation threshold in order to avoid undesirable side effects on the treated surface or in the surrounding areas (swelling of organic materials, selective vaporization of particulates in case of complex crust structures, etc.).

Removal of dark encrustations (pollution accumulations, corrosion layers, excavation crusts) from various substrates (stonework, metal) usually involves infrared (IR) laser systems and relies on photothermal mechanisms. In most cases there is a significant difference in the

absorptivity of the involved materials; this effectively leads to a considerable difference between the encrustation threshold fluence and the one that could potentially damage the substrate, and hence the cleaning process is "self-limiting" (Cooper 1998). Similarly, IR and visible (VIS) laser cleaning methodologies have been proposed for the removal of contaminants and particulates from paper and parchment, as photochemical modifications to the substrates (the cellulose content of paper, or the collagen of parchment) are circumvented in these cleaning regimes.

The photothermal cleaning regime has also been associated with unwanted side effects, for example discoloration. Indeed the yellowing reported upon IR laser irradiation on marble surfaces with pollution encrustation and on natural cellulose materials with carbonaceous contamination has seriously compromised lasers as cleaning tools. Several hypotheses have been introduced to explain such discoloration; the presence and nature of soiling particles have a key role in this undesired side effect. Given that no discoloration was observed upon the irradiation of unsoiled papers or parchments, the yellowing is related to laser-induced thermal degradation of cellulose or collagen, which is due to the presence of the soiling particles that may enhance or favor excessive heating phenomena. In stonework conservation, yellowing is a very complex issue for many reasons—it can be due to the complexity of the materials involved (including in past conservation treatments), to the popularity of laser cleaning in the field, and to the high number of cleaning projects—and therefore many studies were devoted to its explanation.

Along these lines, the synchronous use of IR (1064 nm) and ultraviolet (UV, 355 nm) laser pulses was shown to be able to overcome discoloration effects upon the removal of pollution crusts from marble (Pouli et al. 2012) and was thus successfully applied on the Parthenon sculptures in Athens. The success of this cleaning scheme is based on the combined action of two discrete ablation mechanisms, exemplified by the use of laser pulses of two wavelengths, in spatial and temporal overlapping and in various fluence ratios (F_{IR}/F_{UV}). Both the careful choice of the ratio of applied energies and the individual fluences of each wavelength are decisive for optimum results.

Discoloration (darkening) is also encountered upon direct laser irradiation of painted surfaces. The sensitivity of many pigments to light and temperature is particularly relevant when considering intense laser irradiation, which upon interaction can lead to the localized and rapid heating of the pigment. Significant research has been devoted to the understanding of these undesired side effects and to the definition of the boundary conditions in which laser cleaning can be safely applied on painted surfaces (Pouli et al. 2012). It has been shown that in most cases the darkening of pigment particles is independent of the wavelength of the applied radiation or of the binding media but can be significantly controlled for ultrashort irradiation regimes. It should be also noted that, although the perceived color change is often intense, pigment discoloration usually refers to the outermost particles of the paint, and thus the straightforward identification of the associated physicochemical modifications is extremely surface-specific and particularly difficult.

Along these lines, in paintings conservation UV lasers are employed to eliminate the outermost surface of the aged or degraded natural or synthetic varnish coatings (Pouli et al. 2010). For example, the laser-assisted removal of the outermost cross-linked hard varnish layers using a KrF Excimer laser beam (248 nm), which is strongly absorbed by the majority of aged varnishes, is well studied, while it is confirmed that the mechanisms governing this layer-by-layer cleaning scheme are mainly of a photochemical nature (bond breaking and dissociation) and any thermal effects (heat generation and diffusion) are negligible. In parallel, to support this approach and to investigate quantitatively the extent of chemical modifications that may be induced in the remaining material after ablation, a series of studies using technical samples composed of polymeric films doped with low concentrations of well-defined photosensitive molecules were undertaken. The laser-induced fluorescence of the photoproducts on the irradiated surfaces was monitored in a pump-probe scheme, with the aim of studying the evolution of chemical modifications and their dependence on parameters such as the applied laser fluences, the number of pulses, and the material properties (Georgiou, Anglos, and Fotakis 2008). Technical samples of higher complexity (series of layers simulating the

different strata of real easel paintings and icons) were also investigated, while other cleaning regimes (e.g., ultrashort pulses) or wavelengths were also examined with encouraging results.

Ultrashort (picosecond (ps, 10^{-12} s) and femtosecond (fs, 10^{-15} s)) lasers have been introduced in conservation research because they offer particular capabilities for material processing and overcome several of the nanosecond (ns, 10^{-9} s) laser ablation limitations (Pouli et al. 2010); they may process even nominally transparent substrates (owing to multiphoton processes), while thermal degradation phenomena are significantly eliminated. As a result, the morphological aspects of the fs-processed substrates are far superior to those attained with ns laser pulses, and thus ultrashort laser material ablation is considered to offer greater control and confinement.

Other laser cleaning methodologies involve the use of far-IR wavelengths (2940 nm) emitted from an Er:YAG laser (Andreotti et al. 2007). This cleaning scheme, initially introduced for the removal of varnishes and overpaintings from easel paintings, relies on the selective excitation of molecules that contain hydroxyl (OH) groups and is clearly differentiated from mechanisms of lasers operating in the UV, VIS, and near-IR range. Gradual and selective cleaning of very thin layers is achieved if and only if organic solvents are employed on the surface before and during the laser irradiation.

Laser cleaning is an established and most valuable cleaning methodology, with numerous successful applications in the conservation of CH objects and monuments. Its superiority to alternative cleaning techniques (e.g., solvent and mechanical cleaning) lies in its ability to ensure effective cleaning and minimal chemical alterations to the underlying and adjacent material.

Nevertheless, given the irreversible nature of this process, lasers, like all cleaning tools, should be cautiously employed, to prevent unpredicted mistakes and irreparable damage, and should not be considered as a panacea or a trivial procedure. In this respect it is advisable, prior to any laser-cleaning intervention, to carefully define the conservation problem, determine the physicochemical properties of the materials involved, and set and optimize the working parameters of laser cleaning through preliminary studies and

thorough an assessment of related laser tests. In situ and online monitoring of the laser ablation process is also advisable, in order to ensure a safe and controlled cleaning, with high spatial confinement (ideally, restricted to the beam size) and depth resolution (of submicron level).

Microchemical Tests in Conservation

NANCY ODEGAARD

University of Arizona, USA

Chemical characterization or spot testing is particularly important for the qualitative identification of archaeological and historic materials undergoing examination and treatment. Some forms of physical information may not survive these activities, so it is useful to identify and record as much material information as possible prior to any changes due to cleaning or consolidation. Archaeological conservators are frequently confronted with decisions regarding possible stabilization treatments that are dependent on characterizing the compositional materials of an artifact. In an excavation situation, there may not be time, funding, or access to instrumental techniques for material identification beyond the use of the human eye. Less expensive microchemical spot tests, however, often provide the needed information because they do not require elaborate instruments or specialist participation. While standardized instructions and techniques for reagent preparations and application are sometimes considered old fashioned and are no longer taught, spot tests remain a practical, sensitive, and useful tool in archaeology.

The characterization of distinctive qualities or characteristics of various materials begins with questions concerning the specific nature of an artifact material, its technology, and aspects of its condition (such as deterioration). Specific artifact materials to be considered might include metals, ceramics, plasters, glasses, stone, pigments, bone, wood, fibers, gums, resins, and miscellaneous accretions. Tests for metals may identify hardness, color, or alloying. Tests for ceramics may correlate aspects of contaminant salts, temper, inclusions, or porosity to condition. Chemical tests are useful for distinguishing marble, plasters, shell, and calcareous accretions. Inorganic coatings may be identified by tests that

differentiate carbonates, sulfates, and chlorides. Tests for organic coatings, deposits, or adhesives may distinguish proteins, starches, gums, and resins. Specific tests for the materials that are contextual to the artifact might include analysis of the soil or ground water and dissolved solids. Various tests for soluble and semisoluble salts and pH are useful in a number of contexts. The material characterization of the supplies used in conservation treatments is also important and may include tests for water purity, adhesives, coatings, and storage materials (plastics, papers, labeling materials).

Beginning in the twentieth century, various tests were developed for microchemical analysis, but few were recorded to characterize the composition of materials found in archaeological contexts. The major developments and subsequent revisions of systematic chemical spot-test analysis by Fritz Feigl (1937) and Arthur Vogel (1937) remain important references for isolating organic and inorganic materials. Typically, these spot-test reactions have been successfully applied in clinical analysis, air quality testing, food and water analysis, geochemical prospecting, and forensic laboratories. However, within the literature of these disciplines, the style of test format varies considerably, thereby making it difficult to compare testing of the same materials by different tests. Moreover, most of these test descriptions are limited to chemical procedures that were designed for use by chemists who would not necessarily need reminders of such aspects as reagent preparation, storage, and safety, or the chemical principles involved. The role of the archaeological conservator is to prepare and interpret test results, as well as identify the potential damages that can occur to artifact samples as a consequence of doing the tests.

Despite the rapid application of modern instrumental analytical techniques such as chromatography, mass spectroscopy, and electroanalytical analysis, the search for simpler, safer, and less expensive tests has continued to be important for many applications in archaeology. In recent decades, much of the research in spot

DOI: 10.1002/9781119188230.saseas0378

tests included reviews of older tests. The early work of Friedlieb Runge in 1842 as reported by Anft (1953) involved the use of impregnated papers to accommodate a scientifically checked spot reaction and he is credited with producing the first spot-test papers. In the discipline of conservation, Rutherford Gettens and George Stout developed and refined numerous tests for the analysis of artist materials. Unfortunately, most of their research on microchemical analytical techniques remains in the form of an unpublished notebook located in the Fogg Museum at Harvard University.

Following developments in analytical instrumentation, a reliance on chemical characterization techniques has declined. However, because of the demand for easy, safe, and economical testing techniques, commercial chemical companies have been encouraged to produce simple and compact spot-testing systems. Many new special spot-testing papers have applications in answering questions posed with historic and artistic artifacts. In pottery there are questions that relate to the pigments used for designs, the composition of temper, the nature of inclusions, the composition of efflorescing salts, or the types of residues associated with the object. Aspects of groundwater contamination or the possible presence of fertilizers if the excavation site has also been used for agriculture can be tested. In organic materials it is possible to chemically distinguish if a plant material is a leaf fiber or stem fiber, or if a residue is animal or plant based.

While once the fundamental technique of analytical chemists, spot testing can be useful to nonchemists seeking a safe and easy way to perform analysis. An understanding of exactly what is being tested for is the first stage. For example, a test to identify black pigments on pottery (Nelson 1975) actually identifies the iron component of black pigments in order to distinguish them from carbon-based pigments that are also found on pottery. Knowing that the identification of iron is the key concept in this example makes it apparent that there are broader applications for this particular test beyond pottery color determination. Most tests work best if the question is based on the presence of a material rather than a broadly based "What is it?" type of question.

Although the theory of materials characterization has been discussed in recent years

among excavation conservators, a systematic methodology for microchemical testing was not published until 2000 (Odegaard, Carroll, and Zimmt) and a subsequent edition (2005) directs their application towards conservators, archaeologists, and museum specialists. Prior to these compendiums, there was a general mistrust of chemical tests and a reluctance to use them in archaeology because they were often based on inaccurate, incomplete, and poorly written class notes and hand-outs with multigenerational photocopies from unreferenced publications. For example, many of the earlier chemical spot-testing instructions failed to identify or explain interference materials, or to elaborate on the various chemical processes and stages of a reaction. Additionally, it was common to report the color designation of a positive reaction but neglect to indicate how long a reaction could take or what a negative reaction might appear as.

Important modifications to the recommended reagents and their application techniques make these tests less damaging to objects or samples. Archaeological conservators have found ways to change the way chemical spot testing is done and they understand why it is difficult to use standard chemical testing references that are designed for other situations. There is finesse to finding a suitable and unobtrusive place for the testing on artifacts. Unfortunately, even the most delicate of tests can scar an object, so if the test can take place on a different surface, the chemical reagents will not damage the object itself.

The idea of transferring part of the object's material to another substrate and doing the test on that substrate is the key to saving an object from further damage. For example, the use of filter paper dampened with de-ionized water can facilitate the capture of tiny pigment particles fallen from an object or found in a storage container. Thus, the tiniest particle can be tested with no further loss of pigment from the artifact. Another technique involves using tiny pinhead-sized pieces of filter paper pulled from the edge of a larger sheet. Rather than placing chemical drops directly on the artifact, the reagent can be added to the small paper which can then be placed strategically on the artifact. This technique is particularly useful on artifacts as they tend to have more irregular surfaces than normal laboratory test blanks. Also, reagents

that have low surface tension may flow readily over the surface of the object and spread from an inconspicuous test area to other areas, possibly causing damage to the artifact. By using the tiny filter paper modifications there is greater control of the reagent.

The critical component for comparing the reactions is the use of a known positive sample and a known negative sample with the unknown artifact sample. These are important for developing confidence with a test. Having known samples that can be tested with repeatability is a critical part of a microchemical test. If a reaction is the same for the known positive, the known negative, and the unknown, there is a problem. It might be the analyst, the reagent, the technique, or contamination. The problem of contamination would be impossible to detect if only the unknown was tested. By using the knowns, a positive result on all samples would indicate that the test was inconclusive and the test process would have to start over.

Spot-test plates are available in ceramic (light and dark) or clear glass with varying numbers of testing wells. A white one is useful if the anticipated reaction is colored or dark, and a dark plate is necessary when there will be a white precipitate or a light-colored reaction. Sometimes there is a subtlety in the color of the reaction solution and a clear plate is useful because a light source can be manipulated against a variety of backing materials. For some tests the etched end of a microscope slide is useful. Capillary tubes and Pasteur pipettes can be used to create a sample chamber that isolates the smallest of sample materials. When placed in the funnel part of the pipette, the tiny particle of sample can be tested with spot-testing papers, while the chamber facilitates viewing of the test paper reaction, particularly if pyrolysis is involved as there is time to examine changes in sample color or form, or to detect an odor afterwards. Safety in spot testing involves the use of personal protective equipment and proper reagent disposal for the small amounts of solvents and chemicals that are used.

The reporting of microchemical test results is the critical and final part of the process. Documentation allows for review and comparison of a test procedure and the results over a wide span

of time. When a reaction is unusual, it is possible to go back to the notebook or file and check if that reaction has occurred before. A reliance on sophisticated instrumental techniques of analysis requiring outside specialists to answer many fundamental questions is very useful when it is available, but there are many questions that can be answered with well-defined spot tests.

Mineral Inorganic Treatments

MAGDALENA BALONIS

University of California, Los Angeles, USA

Consolidation is one of the most important steps in the conservation process of deteriorated objects as it re-establishes cohesion between disintegrated particles of powdery surfaces. Extensive studies carried out over the course of past decades have indicated that choosing a proper consolidant to regenerate cohesion of loose or friable surfaces of porous materials such as stone artifacts, wall paintings, or archeological bones is critical and at the same time extremely challenging. This is specifically related to being able to ensure sufficient penetration beneath the surface layer, while also providing mechanical strength and abrasion resistance. Consolidation is normally carried out through the application of liquid solutions, which are placed in contact with the damaged surface and allowed to interact with the material through various physical and chemical processes. The end product, which is formed as a result of these reactions, helps to mitigate the capacity for movement between very small particles of originally weakened surface, thereby altering the characteristics of the material in terms of its physical–chemical behavior, particularly in the presence of water (permeability). It tends to make the material stronger in compression and tension but may also affect inherent characteristics, such as heat and sound transmission, rigidity, or optical properties. An optimal consolidant has to be environmentally friendly, suitable for object or site application, should not severely alter the original “nature of the porosity” (clog pores), and cannot be extremely hydrophobic as this could lead to further damage. Ideally, the consolidant should also be photochemically stable to prevent optical changes of the surface that could affect significantly the saturation of color, gloss, and texture. Other key factors considered in the consolidation include

compatibility of the thermal expansion coefficient with treated material, and retreatability, which is enabling future treatments (if necessary), or good resistance towards biodegradation and physical or chemical environmental effects (wind or sand abrasion, chemical attack such as chloride or sulfate ingress or acid rain).

Starting from around the middle of the twentieth century, organic polymers, mainly acrylic, vinyl, and silicone based, have been widely used as consolidants for heritage objects. However, in many cases, polymers used for the consolidation exhibited poor penetration, and being chemically incompatible with the original surface often induced further degradation of the artwork by changing greatly the physical–chemical properties due to hydrophobicity, embrittlement, yellowing over time, shrinkage resulting in delamination, blocked pores, and so on. As such, various alternative methods to organic polymers which are based on the application of inorganic mineral treatments have been proposed (Hansen et al. 2003; Matteini 2008). These approaches have proven to be often more suitable given the original nature of many artifacts such as wall paintings and calcareous stone objects.

Historically, limestone-based antiquities and wall paintings, particularly those of fresco application, have been treated with a saturated calcium hydroxide solution (“limewater”), which eventually resulted in a calcium carbonate formation. The consolidation mechanism of this method is based on the transformation of $\text{Ca}(\text{OH})_2$ into calcium carbonate (CaCO_3) through a carbonation process induced by the CO_2 in the atmosphere following chemical reaction, as shown in Table 1. However, because of the limited solubility of calcium hydroxide (1.73 g/L at 20 °C), limewater has to be applied in successive applications to ensure sufficient deposition of the consolidant. Multiple treatments, however, may block pores and alter the natural “breathing” of the surface while reducing penetration of the consolidant. Furthermore, low stability of the system and high surface tension of water (as the medium) can also cause aggregation and phase separation. All these may

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0384

lead to insufficient consolidation and aesthetically undesired “whitening” of the surface.

Further risk associated with this method is linked to the introduction of large amounts of water, which may mobilize soluble salts (if any are present in the system) and induce additional stresses through dissolution and recrystallization or freezing and drying processes (Hansen et al. 2003). As solubility of $\text{Ca}(\text{OH})_2$ is inversely proportional to the temperature, to maximize concentration in the solution, colder temperatures have been suggested. However, maintaining such conditions can be a challenging task from a practical perspective. As such, in search for improvements, several strategies including “sucrose methods” to increase $\text{Ca}(\text{OH})_2$ solubility and the synthesis of $\text{Ca}(\text{OH})_2$ nanoparticle–alcohol dispersions (Ambrosi et al. 2001; Rodriguez-Navarro, Suzuki, and Ruiz-Agudo 2013) to prevent agglomeration and boost penetration have been explored. It has been demonstrated that the synthesis of $\text{Ca}(\text{OH})_2$ particles exhibiting size lower than 300 nm and their proper dispersion in suitable solvents allowed for the improved penetration through the surface layer of the object. Solvents such as ethanol or propanol yielded slower sedimentation and agglomeration rates in comparison with aqueous media and reduced the risk for the formation of a white veil on the surface. Examples of such a successful consolidation were shown by Ambrosi et al. (2001). $\text{Ca}(\text{OH})_2$ has also demonstrated good compatibility when used as a de-acidifying agent in the conservation of paper and water-logged wood where formed CaCO_3 acted as an effective alkaline reservoir. Nanostructured $\text{Ca}(\text{OH})_2$ was also tried as a consolidant for demineralized archaeological bones and it was noted to increase their strength when compared to the untreated samples. Yet, in spite of improved working and resulting satisfactory outcomes, there are several drawbacks associated with this consolidation method. First, the pH of $\text{Ca}(\text{OH})_2$ solution is quite high (~ 12.5) so it can affect some of the pigments used to make the artifact, which are sensitive to alkaline conditions. Second, while color changes are less of a concern in case of stone consolidation, dissolution of CaCO_3 upon a drop in the pH caused by acid rain and other acid local environments, especially when the object or monument is placed outdoors, could be a problem.

Potential phase transformation into gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) in the presence of sulfate ions (known as “sulfation”) poses another limitation on the use of $\text{Ca}(\text{OH})_2$ -based consolidants. When large amounts of soluble sulfates (e.g., sodium or magnesium sulfates) are present, for example in a wall painting, sulfate ions may react with calcium hydroxide, producing slightly soluble gypsum. The final result is the lack of consolidation effect and an unwanted formation of white crusts resulting from the newly formed gypsum salt.

For many years, the barium hydroxide method (Hansen et al. 2003; Baglioni and Giorgi 2006; Matteini 2008) has been considered an alternative and improved consolidation treatment to the calcium hydroxide method, as atmospheric carbonation enables formation of a barium carbonate consolidating layer of relatively low solubility. To address the problem of sulfation, the barium hydroxide ($\text{Ba}(\text{OH})_2$)-based treatment, also known as the Ferroni–Dini method or the “Florentine method,” was developed following the disastrous flood of Florence in 1966. This treatment employs a two-step process to block sulfates present in mobile form and to consolidate through the atmospheric carbonation process (Table 1). An example of the restoration performed on a wall painting using this method was demonstrated by Baglioni et al. (2008). First, gypsum is transformed with a solution of ammonium carbonate that converts it into calcium carbonate and soluble ammonium sulfate. In subsequent treatment with barium hydroxide, the ammonium sulfate is converted into barium sulfate which is an inert and insoluble salt. In this way sulfation is arrested. Owing to the new formation of barium carbonate and barium sulfate, the porosity is reduced and the system is expected to be less susceptible to the environmental pollutants, soluble salts intrusion, or even potentially acid rain dissolution. However, proper application procedures must be followed to prevent whitening or “bloom.” For all these reasons, barium compounds have been considered desired consolidants due to their compatibility with a substrate, minimal effect on the appearance, preservation of the original hydrophilic properties of the surface, and effectiveness in transforming gypsum into an insoluble salt. It has been noted, however, that there are also several drawbacks associated with barium treatments:

Table 1 Basic chemical reactions associated with inorganic consolidation treatments.

<i>Inorganic consolidant</i>	<i>Basic chemical reaction(s)</i>	<i>Action</i>	<i>Remarks</i>

(NH ₄) ₂ HPO ₄ (NH ₄) ₃ PO ₄	$\begin{aligned} &10\text{CaCO}_3 + 6(\text{NH}_4)_3\text{PO}_4 \rightarrow \text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 \\ &\quad + 18\text{NH}_3 + 10\text{CO}_2 + 8\text{H}_2\text{O} \\ &10\text{CaCO}_3 + 6(\text{NH}_4)_2\text{HPO}_4 \rightarrow \text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 \\ &\quad + 18\text{NH}_3 + 10\text{CO}_2 + 8\text{H}_2\text{O} \end{aligned}$	Consolidation Consolidation Desulfation	In a real-world scenario, HAP is anticipated to precipitate as nonstoichiometric salt where PO ₄ ³⁻ and/or OH ⁻ groups are replaced by CO ₃ ²⁻ . It can also be calcium deficient where Ca ²⁺ ions are partially substituted by NH ₄ ⁺ . Matteini et al. (2011) also proposed (NH ₃)H ₂ PO ₄ as consolidating agent, but to offset lower pH associated with this consolidant their system was equilibrated with addition of NH ₃ .

(1) They are not appropriate for substrates rich in magnesium carbonates (plasters made with dolomitic lime or dolomitic marble statues) due to the formation of highly soluble magnesium sulfate (Hansen et al. 2003); (2) when nitrates are present (due to the precipitation of insoluble barium nitrate); and (3) they can cause chemical changes to the copper-based pigments. Additionally, the high alkalinity of barium hydroxide can severely damage organic binding media such as egg tempera if any are present in secco mural paintings. There are also questions and concerns related to the toxicity of barium, and not all nations permit the use of barium in conservation.

In the early 1990s, calcium oxalate-based treatment was proposed (Hansen et al. 2003; Matteini 2008). This method, inspired by the observation of naturally formed oxalate patinas, was developed mostly for the historic objects and monuments subjected to the outdoor environment where acid rain and following dissolution of carbonate material are points of concern. As such, the formation of a protective oxalate layer due to its reported low solubility and high stability in a wide pH range (Matteini 2008) is expected to mitigate this dissolution and act as an ideal passivation agent for calcium carbonate objects subjected to urban acidic atmosphere. Oxalate treatment employs highly soluble ammonium oxalate solution through the application of a cellulose poultice compress subsequently placed on the calcium carbonate-based surface. As a result of this interaction (Table 1), protective film consisting of fine calcium oxalate crystals is produced. Oxalate treatment can also act as an effective desulfating agent (Table 1) as it reacts with gypsum in a similar way as it reacts with calcium carbonate. The ammonium sulfate that remains can be subsequently removed through a desalination process using compresses of deionized water and cellulose pulp. The transformation of gypsum into calcium oxalate is advantageous as it prevents further mobilization, transport, and crystallization of gypsum, which could damage the wall painting or sculpture. Additionally, due to calcium oxalate formation at the surface and subsurface, mitigated penetration of salts into a porous matrix has been recorded. There is, however, a certain challenge associated with this treatment as limited penetration and consolidating effect have been noted. Most notably, yellowing discolorations

in oxalate-treated stones or mortars may occur, mainly those containing free iron (III) in their structure. The ammonia present in the precursors may also damage certain copper-based pigments such as malachite and verdigris.

Recent studies have demonstrated a considerable potential for developing much improved inorganic consolidation treatments by biomimicking the growth of hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, HAP) on calcium-rich matrices (Sassoni, Naidu, and Scherer 2011; Balonis and Kakoulli 2013; North, Balonis, and Kakoulli 2015). Hydroxyapatite is the main mineralogical component of teeth and bones responsible for their strength and rigidity. As such, when induced as a consolidant it results in improved mechanical properties of the surface/subsurface, as well as reduced water sorptivity without clogging pores or causing whitening on the surface. It has very low solubility and exhibits good stability in pH ranges from approximately 4 to 14, which like the oxalate treatment makes it suitable for outdoor applications. Formation of a protective HAP crystals network is induced by triggering reactions between the calcium in the calcium carbonate-rich matrix and highly water-soluble ammonium phosphate precursor (Table 1). This aqueous solution can be introduced through spraying techniques or cellulose poultice; the latter seems to provide a better control of application technique and homogeneity in the distribution of the final product. Calcium ions are not anticipated to reprecipitate as calcium carbonate due to the fact that the solubility product of HAP ($\log K_{\text{sp}} = 1.6 \cdot 10^{-117}$) is much lower than that of calcite ($\log K_{\text{sp}} = 3.4 \times 10^{-9}$). This treatment has also demonstrated better penetration into porous materials when compared to the oxalate-based consolidation (Sassoni et al. 2011; Balonis and Kakoulli 2013). In addition to consolidation, ammonium phosphate salts are anticipated to serve as desulfurization agents, converting damaging gypsum into HAP (Table 1). However, at lower pH conditions or when not enough calcium is available to form hydroxyapatite, other calcium phosphate salts such as brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) may also form. The method is especially encouraging when it comes to the consolidation of wall paintings, containing pigments and binding media (e.g., egg tempera)

that exhibit sensitivity to a high pH. The selection of a proper precursor such as diammonium phosphate $((\text{NH}_4)_2\text{HPO}_4)$ solution at pH of approximately 8 allows for the prevention of aggressive alkaline conditions. Apart from wall paintings and outdoor monuments, hydroxyapatite consolidation has also shown promising results for archaeological bone conservation (North et al. 2015) as due to its nature it is more compatible with original material and may serve as a great alternative to polymeric consolidants, which are commonly used for bone, teeth, fossil, or ivory preservation. However, several things need to be kept in mind when using this method. First of all it involves ammonia which can cause damage to copper-based pigments. Additionally, to avoid aesthetically undesirable whitening of the surface, pigment degradation, or blocking pores which can be detrimental, treatment should be designed with regard to appropriate ammonium precursor type, concentration, and time of contact (Balonis et al. 2013).

In conclusion, when considering consolidation, “not one size fits all,” as reaction chemistry (type of consolidant, concentration, pH, additives), as well as application method (poulticing, spraying, immersion) and time have to be tailored to the specific objects, bearing in mind their chemical nature (including binding media present if any, impurities, pigments) and exposure conditions (outdoor, indoor, temperature, pollutants, acid rain, etc.). In addition, from a practical perspective, toxicity of treatment and feasibility of application technique need to be considered.

Nanotechnology and Nanoscience in Conservation

PIERO BAGLIONI, DAVID CHELAZZI, and
RODORICO GIORGI
University of Florence, Italy

The importance of preserving material heritage has been acknowledged worldwide, as cultural and historical patrimony are sources of different benefits that comprise social inclusion, the transfer of aesthetic and ethical values to future generations, and economic improvement thanks to tourism and to the valorization of well-conserved artifacts. Science offers several possible solutions to the preservation of works of art, and research work in this field has mainly followed two distinct lines, namely the development of enhanced diagnostic techniques for the analysis of the artifacts, and the synthesis and formulation of materials to counteract the degradation of the works.

Significant effort has been dedicated to the development of advanced diagnostic methods with key features such as noninvasiveness of the analysis, enhanced detection limits (high sensitivity and specificity), feasibility (e.g., user-friendly software for end-users), and the use of portable instruments. Techniques such as laser-induced breakdown spectroscopy (LIBS), surface-enhanced Raman scattering (SERS), synchrotron-radiation-based X-ray techniques (Bertrand et al. 2016), nonlinear imaging spectroscopy (e.g., second and third harmonic generation (SHG and THG), multiphoton excitation fluorescence (MPEF), and fluorescence-based techniques), reflectance hyperspectral imaging, fiberoptic reflectance spectroscopy (FORS) (Cucci, Bigazzi, and Picollo 2013), diagnostic immunology (Cartechini et al. 2010), and multianalytical approaches (for instance combining thermal analysis with infrared spectroscopy, gas chromatography, and mass spectrometry) are

all examples of diagnostic tools that have been developed in the last decades according to one or more of the aforementioned criteria.

As a complementary research line to diagnostics, the development of advanced conservation materials saw significant improvement in the last decades in the framework of material, colloids, and nanosciences. This approach has developed since the 1980s, when urgent solutions were needed to remedy the damage suffered by precious artifacts in the aftermath of the 1966 Florence and Venice floods. Accordingly, the first methodologies were developed to tackle the conservation of fresco paintings and stone, in particular focusing on the removal of salts and other detrimental layers from the original surface of the artifacts, and on the mechanical strengthening of powdering and delaminated layers. Starting with these examples, several materials and methodologies have been developed in the framework of soft matter and colloids to achieve the cleaning, consolidation, and pH adjustment of degraded works of art, where fundamental requirements are the compatibility of the new materials with the original artifacts (whose physico-chemical properties must be altered as little as possible) and the minimal (or no) impact of the new materials on both the environment and the operators (conservators, curators, etc.). Two books have been published that illustrate the most important advancements in this topic (Baglioni and Chelazzi 2013; Baglioni, Chelazzi and Giorgi 2015a).

The cleaning of artifacts, intended as the removal of any detrimental or unwanted layer, is typically carried out as a preliminary intervention before other applications (e.g., consolidation) are performed. Advanced systems for this task have been derived from colloids science and soft matter, and comprise microemulsions and gels. The main advantage of these systems is that they grant improved performances as opposed to traditional cleaning materials such as solvent blends and thickeners. Microemulsions were applied for the first time on Renaissance wall paintings in the late 1980s, for the removal of wax spots (coming from votive candles) that were

jeopardizing the painted surface (Baglioni and Chelazzi 2013). The rationale of this method is as follows: Low amounts of solvents (typically less than 10% w/w) can be dispersed as microemulsions (using surfactants) in a continuous water phase ("oil-in-water" systems, o/w). Knowing the phase-diagram of the composite system, it is possible to formulate cleaning fluids that are thermodynamically stable, optically clear, and isotropic, where the size of the microemulsions' droplets is in the order of nanometers. Such a small size grants a dramatic increase of the active surface area of the solvent droplets. These fluids can be applied either with a swab or loaded in poultices and gels. Surface dirt and soil tends to swell or dissolve in the fluids, becoming embedded within the micelles. The latter migrate into the poultice/gel, favoring the removal of the unwanted layer from the surface of the artifact. This is a key feature as opposed to the use of free solvents, where dissolved dirt or compounds tend to migrate within the porous matrix of artifacts (e.g., wall paintings, stone) and are not removed from the object. The microemulsion's droplets are also able to exchange solvents and surfactants with the soil or aged adhesives, which are consequently swollen and softened. The swollen layers can be removed with a gentle mechanical action, which grants a gradual and controlled removal. Another key advantage is that good cleaning effectiveness can be achieved while lowering the total amount of solvent needed in the cleaning system, as mentioned above, which addresses the well-known toxicity issue of most solvents used in the restoration practice. Finally, because they work through a different removal mechanism than that of free solvents, both micellar solutions and microemulsions have proven effective in some cases where the mere use of solvents did not allow the removal of complex layers of aged and detrimental adhesives or consolidants from past restorations (Baglioni et al. 2015a). Current improvements involve the presence of degradable surfactants (either biodegradable or cleavable) in the cleaning fluids, in order to avoid any rinsing step to eliminate nonvolatile residues from the treated surfaces. Microemulsions have been used in many real conservation case studies, and an example of the cleaning obtained with these systems is shown in Figure 1.

A limitation to the use of aqueous nanostructured cleaning fluids concerns their application onto highly water-sensitive surfaces. This is not usually an issue for wall paintings and stone, but can be problematic when cleaning paper artworks or easel paintings, where the dyes or the color binders are sensitive to water (e.g., acrylic paintings). While nanostructured cleaning fluids can be prepared also by dispersing aqueous solutions in nonpolar organic solvents (w/o), these fluids can exhibit decreased capability of removing soil and in some cases contain higher amounts of surfactants than o/w systems (Ormsby et al. 2016). A possible solution for using o/w microemulsions on water-sensitive surfaces is to confine the fluids within highly retentive matrices, such as those of polymer networks. Traditionally, polymer thickeners such as polyacrylic acid or cellulose derivatives have been used to make networks that are held by secondary bonds (hydrogen bonds, polar forces, Van der Waals interactions) between the polymer chains. These systems allow effective cleaning and reduce the spreading of fluids; however, they tend to leave polymer residues (Casoli, Di Diego and Isca 2014) owing to the lack of strong interactions (e.g., primary bonds) between the polymer chains, which results in poor viscoelastic behavior. Besides, several of these “gel-like” thickeners are not retentive enough to allow the gradual release of loaded aqueous fluids or solutions on water-sensitive substrates such as dyed and inked paper or canvas (Baglioni et al. 2015a). Alternative confining systems have been developed in the framework of soft matter and colloids science. Examples include chemical gels where the polymer network is held by covalent bonds (cross-links) between the polymer chains, and where polymer blends are formed by embedding linear or branched polymers into one or more polymer networks during the polymerization reaction (interpenetrating polymer networks (IPNs)). The composition and degree of cross-linking of the network can be tuned, resulting in different mechanic (viscoelastic) properties, porosity, and affinity to water or polar solvents. This allows the formulation of gels that can be easily handled, applied, and removed from the artistic surface without leaving polymeric residues (for instance as detectable with infrared spectroscopy). Controlling the porosity and

the composition of the gel network also allows tuning of the retentiveness of the gel when it is loaded with aqueous fluids, which grants the safe and controlled treatment of inked paper works and poorly bound painted layers on canvas paintings.

Finally, in cases where the use of aqueous fluids is not convenient, organic solvents can be confined in organogels, which limit the solvents' volatility (and thus their impact on the health of operators) and allow the controlled release of the solvents on artistic surfaces. Recently, chemical organogels based on the cross-linking of methyl methacrylate (MMA) have been used for the first time to remove varnishes from the surface of canvas paintings (Baglioni et al. 2015b). The gels were loaded with solvents with average polarity such as methyl ethyl ketone, cyclohexanone, ethyl acetate, and butyl acetate, which are capable of swelling or dissolving several natural (terpenic resins) and synthetic (vinyl acetate and acrylate copolymers) coatings frequently met in the conservation practice. The loaded gel is applied for a short time to the surface (e.g., for one minute or less), and as a result the coating is either dissolved (and migrates into the gel) or swollen, and then removed with a gentle mechanical action.

Altogether, microemulsions, micellar solutions, and chemical hydrogels and organogels have expanded consistently the palette of tools that are nowadays available to conservators for the cleaning of works of art. However, while the removal of soil and detrimental layers provides aesthetic improvement and prevents further degradation of the artifacts, the cleaned surfaces can still be in need of consolidation as their mechanical properties are worsened by natural aging, weathering, and degradation from detrimental consolidants used in past restorations.

The first solution developed in the framework of colloids and nanoscience for the consolidation of works of art concerned the synthesis of nanoparticles of calcium hydroxide for the strengthening of carbonate-based wall paintings and stone. This approach is alternative to the use of traditional consolidants and adhesives such as acrylate-vinyl copolymers used since the 1960s. In fact, these polymer coatings alter strongly the physico-chemical properties of murals and stone,

with particularly detrimental effects when salts pollute the porous matrix of the artifacts. In such case, salts crystallize between the coating and the artifacts' surface, leading to mechanical stress and to the disruption of the surface layers. The polymer coatings can degrade in turn, exhibiting yellowing and loss of adhesion owing to natural aging. Instead, calcium hydroxide ($\text{Ca}(\text{OH})_2$) is an ideal material for the consolidation of carbonate-based substrates, because it is able to react with atmospheric CO_2 (carbonation process), recreating a network of carbonate within the pores of weakened artifacts, through a process that mimics the setting of a fresco. The newly created carbonate network provides mechanical strength and matches the chemical and physical properties of the original artifacts, minimizing drawbacks in the long term. However, the scarce solubility of $\text{Ca}(\text{OH})_2$ in water hinders the use of aqueous solutions of hydroxide, which exhibit only poor consolidating power. An effective solution was then to disperse $\text{Ca}(\text{OH})_2$ as nanoparticles in nonaqueous solvents such as short-chain alcohols (ethanol, propanol). This allows the direct delivery to the artifacts of higher amounts of hydroxide as opposed to aqueous solutions, with a dramatic increase in the consolidating power. Another significant advantage is that the use of dispersions avoids the presence of a large excess of free, mobile hydroxide ions delivered all at once on the surface, which can be detrimental to alkali-sensitive pigments in the painted layers of the murals. Dispersions of calcium hydroxide nanoparticles have been successfully used in numerous case studies in the last decades (Figure 2), and the best procedures have been set, including practical tips and applicative protocols to maximize the penetration of the particles, favor the carbonation of hydroxide, and avoid the formation of white veils on the treated surface.

The application of the particles is typically carried out after removal of the majority of the salts that pollute the mural or stone; otherwise the presence of some electrolytes (e.g., soluble sulfates) might hinder the consolidation effect. In particular, the consolidation of stone involves some challenging aspects as compared to that of murals, namely the penetration of the particles through the stone matrix can be hindered by several factors, for instance oscillations in temperature and relative humidity can lead to

condensation of water in the pores, which makes particles stack, hindering their homogeneous penetration (Baglioni et al. 2015a).

Dispersions of alkaline earth hydroxides have been also applied since the early 2000s for the pH adjustment of acidic artifacts such as paper, canvas, and wood, as well as for the consolidation of bone and ivory. Acidity sources are various, including pollution gases hydrating in the fibers' moisture, volatile organic acids developed by adhesives and glues used in repairs, and wooden boxes used for storing the artifacts, acidic compounds used in the papermaking process, inks, and the presence of acidic groups in the cellulose chains owing to the oxidative degradation of the objects. In the case of waterlogged wood (e.g., shipwrecks), acidity can also be due to the presence of sulfuric acid formed after salvage, owing to the oxidation of reduced sulfur compounds that accumulated in the wood when it was buried in polluted water with sulfate-reducing bacteria. The presence of iron ions (from corroding bolts and other metallic parts) favors the oxidation of cellulose and the formation of acids. It was shown that the nanoparticles' dispersions can be feasibly applied (e.g., by spraying, brushing, or immersion), and after the evaporation of the solvent the particles adhere to the cellulose fibers, where they undergo carbonation. An alkaline reserve of carbonate is thus formed to prevent the damage of cellulose from the recurring formation of acids in the fibers' network (Figure 3). The application of particles dispersed in a solvent, rather than of free and mobile hydroxide ions in solution, is less risky to oxidized cellulose fibers that are sensitive to alkalinity, making the method safer than traditional baths with aqueous solutions of alkalis.

The treatment of wood can be more problematic than that of paper and canvas because the thorough and homogeneous penetration of the particles through the wood matrix can be hindered by the presence of consolidants such as polyethylene glycol, traditionally used to prevent the shrinkage of waterlogged wood as it dries (Baglioni and Chelazzi 2013). As a matter of fact, different types of particles have been applied on wood since 2007, including calcium, magnesium, and strontium hydroxide or carbonate, and have resulted in effectively neutralizing the acidity and preventing the formation of acids (Chadwick et al. 2014). Besides, as discussed in a review by

Marzi (2015), various nanostructured materials have also been explored for the protection and reinforcement of timber structures, including clays and oxides used to achieve waterproofing, ultraviolet (UV) protection, biocide, fire resistance, self-cleaning, and anti-scratching properties.

Recently, nanomaterials such as microemulsions, gels, and nanoparticles have been used for

the first time on collaged-based substrates. In particular, historical leather was cleaned from soil and patinas using hydrogels loaded with o/w nanostructured cleaning fluids, and then the pH was adjusted to values that are typical of pristine leather, in order to prevent the acid hydrolysis of collagen (Baglioni et al. 2016).

While much work has been done on the preservation of classic works of art, efforts are currently

being dedicated to addressing the conservation of modern and contemporary artifacts, which exhibit different degradation processes that can be often sudden and highly detrimental. Numerous modern and contemporary artifacts have been realized using materials derived from the industry, which were not meant to last long, and whose complex composition poses challenges to the effective preservation of the objects. Current conservation topics involve the cleaning of modern paintings, plastics, and metals, and the strengthening of both surface layers and supports (e.g., canvases).

Neutron Imaging and Tomography in Conservation

EMMA PAYNE

University College London, UK

An introduction to neutron imaging

Neutrons are subatomic particles with no overall charge; they were discovered by James Chadwick in 1932 and, together with slightly smaller, positively charged protons, make up the atomic nucleus. Neutron imaging is a radiographic technique in which a beam of neutrons is applied to an object (see NEUTRON RADIOGRAPHY AND TOMOGRAPHY). The manner in which the neutron beam is attenuated by the object allows its internal structure to be recorded (Ryzewski et al. 2013, 344). The technique was first developed in the 1930s and 1940s by Hartmut Kallmann and Ernst Kuhn; it was refined by J. Thewlis in the 1950s and continues to evolve to this day (Brenizer 2013, 11). Over the past decade the potential of the technology has rapidly advanced, owing to improved computing facilities and new, more sensitive techniques and sensors. It can be used in both 2D and 3D (tomography) for detailed exploration of objects.

Neutron imaging is a powerful, nondestructive method of object investigation developed primarily for industrial purposes, including for the investigation of nuclear fuel and for aerospace engineering. From the 1970s, its potential contribution to the field of cultural heritage studies has slowly started to be recognized. Its capacity to extract detailed information about the internal structure of an object has important ramifications for conservation, enabling the development of more targeted, individually tailored approaches to treatment. It can then be used for continued monitoring and assessment of the success of treatments applied. However, there are also certain risks and limitations of neutron imaging that

must be considered when evaluating its possible role in any given program of conservation.

The benefits of neutron imaging

A nondestructive investigative technique

For conservators, the primary benefit of imaging techniques for the investigation of objects is the fact that these methods are noninvasive and nondestructive. The physical integrity of the object need not be compromised by the removal of samples. Furthermore, imaging a whole object allows it to be assessed in its entirety, while sample analysis provides definitive information only for that small piece.

Different imaging techniques can be adopted for different purposes. For example, methods using visible light, such as 3D laser scanning and reflectance transformation imaging, can facilitate close investigation of the external morphology of an object and its surface texture (see LASER SCANNING AND REFLECTANCE TRANSFORMATION IMAGING (RTI) IN CONSERVATION). Methods involving other, more penetrative forms of radiation, such as neutrons and X-rays, can facilitate the observation of the internal structure. When used together, these techniques allow comprehensive visualization, recording, and analysis of the entire composition and construction of an object. Visible light techniques are becoming increasingly sophisticated and accessible, and X-ray radiography (see X-RAY RADIOGRAPHY) has long been used by conservators for the exploration of the internal structure of objects. Neutron imaging has been much less widely adopted but can represent a valuable complement to X-ray radiography, providing a superior method of imaging for certain types of material.

A complement to X-Ray radiography

An X-ray or neutron image displays the extent to which radiation has penetrated an object. A beam of radiation is applied to the object, behind which is a photosensitive film or digital detector;

Figure 1 A visual representation of the total microscopic reactions between different elements and different types of radiation applied using tomographic probes. Republished with permission of the author, Andersson, P. 2014. “Fast-Neutron Tomography Using a Mobile Neutron Generator for Assessment of Steam-Water Distributions in Two-Phase Flows. Digital Comprehensive Summaries of Uppsala Dissertations from the Faculty of Science and Technology 1146. Uppsala: Acta Universitatis Upsaliensis.

this records any radiation that has successfully passed through the object. In these images, bright white areas indicate the presence of materials penetrated only to a very limited extent; darker areas signify materials that are more transparent to the radiation applied. However, neutrons and X-rays interact differently with the component parts of any given object. Whereas neutrons interact with atomic nuclei, X-rays interact with the electron cloud (Ryzewski et al. 2013, 344). The diverse nature of these interactions means that neutron and X-ray beams are attenuated to different degrees when applied to the same materials (see Figure 1).

Unlike X-ray radiography, neutron imaging can provide clear distinctions between different isotopes and between elements in close proximity on the periodic table. Moreover, neutrons are typically very good at passing through materials, which are relatively opaque to X-rays, and vice versa. The radiodensity of an object—the extent to which X-rays can pass through it—is connected to both the density and the atomic weight of its composite materials: as density and atomic weight increase, so does radiodensity. This principle does not apply to neutron imaging. While X-rays can easily penetrate materials, including organics, composed from lighter elements, neutrons can

be readily scattered and absorbed by many such elements, including hydrogen, carbon, and nitrogen. Conversely, unlike X-rays, neutrons can easily penetrate layers of dense metal. This behavior of neutrons—their passing through some materials while being absorbed or scattered by others—varies according to their energy. Fast-moving neutrons supplied in a high-energy beam can pass through most materials with ease. For object analyses, it is typically most useful if they can pass relatively easily through metals while being significantly attenuated by light elements. To achieve this, neutrons can be cooled: this reduces their speed and penetrative capacity.

Both X-rays and neutrons can be harnessed to capture 2D images; however, tomographic imaging can also be employed. Tomography is the imaging of the internal structure of objects in section: both computed tomography (CT) scanning, which employs X-rays, and neutron tomography (NT) involve taking a series of cross-section images at multiple, evenly spaced orientations by revolving the radiation beam and the digital detector around the object. The cross-sections are reconstructed to create a 3D model from which cross-section slices (tomograms) can be extracted for analysis (Ryzewski et al. 2013, 345; see X-RAY TOMOGRAPHY and COMPUTED TOMOGRAPHY).

Current uses in conservation

Neutron imaging represents a powerful tool for conservators for a number of important reasons. It is nondestructive and noninvasive, allowing in-depth analysis of the structure and composition of object interiors without the need for sampling. The complementary characteristics of X-ray radiography and neutron imaging mean that conservators may profitably use these two techniques together, or a single technique might be selected if an object is particularly suited to one type of imaging. For example, neutron imaging is very useful for the investigation of organics and hydrogenous materials, for metallurgical studies, and for exploring composite objects comprising substances with low atomic numbers contained within materials with high atomic numbers. This includes organics found within metallic or stone

matrices; and also waterlogged ceramics, leather, and wood. X-ray radiography is of limited use in such cases, since the heavier materials block the view of the lighter ones. These benefits of neutron imaging have made the technique an increasingly attractive option for the investigation of heritage objects before, during, and after conservation treatment.

Before commencing any conservation treatment, neutron imaging can be used as an investigative technique to address technical questions, such as determining the methods of manufacture used to create a given object and the range of craft skills necessary for its production. The answers to these questions can provide valuable insights into the technological capabilities and concerns of a particular society. Neutron imaging is particularly appropriate for investigations centered on distinguishing heterogeneous constituents within metallic artifacts. Therefore the technique can play an important role in compositional and provenience analysis. It can also be used for the detection of organic remains found within closed metal artifacts (e.g., shrines or casks) and for finding the remnants of clay molds on cast-iron objects (Rant et al. 2006, 8). Such information is valuable to archaeologists and conservators alike. As well as providing details of the raw materials and creative processes involved, neutron imaging can help to reveal the behavior of these component materials and the current condition of the object. A condition analysis might include, for instance, the detection of structural flaws, the extent of metal corrosion, and the presence of soluble salts or old restorations. Understanding the condition of an object is essential for both archaeologists and conservators. For the archaeologist, the condition may provide clues as to the function of an object and how it was used and valued over time. These details help the conservator to gain a full understanding not only of the problematic aspects of condition that require specialist intervention, but also of the historical significance of the object: combined awareness of both strands is crucial for an appropriate conservation strategy to be determined.

A conservation strategy will typically involve both preventive and remedial measures. The former might include housing the object in an appropriate, climate-controlled environment, if neutron imaging were to discover the presence

of soluble salts. Neutron imaging might also help guide the handling and packing of objects or the application of remedial measures, for example the introduction of resins for consolidation, based on the pinpointing of any structural flaws. After an initial assessment and the commencement of a conservation strategy, neutron imaging can then be employed to continue to monitor the extent of corrosion or salt issues, to ensure that cracks remain stable, and to evaluate the success of applied remedial treatments. Oils, waxes, and resins—materials used for consolidation treatments—contain high levels of hydrogen to which neutron imaging is particularly sensitive.

Notable recent studies include Krejci et al.'s (2016) research at the Institute of Experimental and Applied Physics, Czech Technical University (Prague). One case assessed the use of neutron imaging to analyze a Roman leather shoe. Neutron imaging enabled detailed analysis of this composite object, clearly showing that the shoe was constructed from several layers of leather and contained iron studs. Lehmann, Vontobel, et al. (2005) conducted neutron imaging of a Roman bronze statue of Mercury from Thalwil (Swiss National Museum, Zurich). This object is composed of thick layers of metal: neutron imaging successfully enabled its structure to be analyzed, while X-ray imaging of the same object produced little information.

Rehren et al.'s (2013) study involved ancient Egyptian iron beads (Petrie Museum of Egyptian Archaeology, UCL, London), which were analyzed at the Budapest Neutron Centre, Hungary. These beads were heavily corroded and their structure was unclear from visual analysis. Neutron imaging revealed the tubular nature of the beads: they were discovered to have a central hole along the long axis—this was now filled with corrosion products but would once have been used for stringing. The images also showed that the beads were constructed from rolled-up iron sheet, and, although badly corroded, the analysis demonstrated that their original structure was preserved (see Figure 2).

The use of neutron imaging to assess the presence of consolidant has been illustrated by Lehmann, Vontobel et al. (2005). Neutron imaging successfully detected consolidant within a knife from the Roman site of Vindonassa (Switzerland); X-ray radiography, by contrast,

had revealed only empty space. Lehmann, Hartmann et al.'s (2005) research has also shown that, in addition to displaying the final distribution of the applied consolidant, neutron imaging can be employed to compare the uptake behavior of various consolidants and solvents when applied to wooden artifacts. Osterloh and Nusser's (2014) work has similarly adopted neutron imaging to investigate the presence of old restoration treatments. In this case, the analysis centers on the use of "carbolineum," a hydrocarbon-based consolidation treatment often employed in the early twentieth century to stop the biological decay of wooden sculptures. This was a noxious material, causing dark staining; it is no longer used by conservators and it is desirable that, where possible, it should be removed from treated objects. Neutron imaging can help assess the distribution of carbolineum and the extent to which it has penetrated the objects to which it was applied; this enables a better assessment of the feasibility of its removal.

Limitations and risks of neutron imaging

The equipment required for neutron imaging is different and, currently, more expensive, more complex, and more hazardous than the one needed for X-ray radiography. The absorption of neutrons from the neutron beam by the nuclei of the constituent atoms of the target object can produce short-lived radioactive isotopes. The length of time for which an object remains radioactive depends on the intensity of the neutron source and on the length of exposure (Rant et al. 2006, 9). It may not, therefore, be immediately safe for an object to be returned to its collection. The Oak Ridge National Laboratory (ORNL) Neutron Sciences Directorate has developed a sample activation calculation (SAC) tool to estimate an object's neutron activation after exposure to a neutron beam. A balance must be struck between the use of a sufficiently intense beam for imaging and making sure that the object does not remain radioactive for an inordinately long spell of time. The aim of the SAC is to ensure that objects can safely be returned to their collections within a year (Ryzewski et al. 2013).

In order to prevent objects from remaining radioactive for lengthy periods and to allow a

Figure 2 Neutron images of iron beads, in side view (left) and perpendicularly (right). Petrie Museum UC10740, UC10739, and UC10738 (from top). clear distinction between easy penetration of metals but widespread scattering and absorption caused by the abundance of lighter elements such as hydrogen and carbon, the neutron beams employed for analysis are typically rather less intense than those produced from X-ray sources. This means that it is difficult to obtain high-resolution images (see Figure 3). Moreover, while neutron imaging is well suited to the analysis of metallic, organic, and composite objects, there are materials for which it is of rather limited use. For instance, the constituents

of ceramic objects do not provide great contrast in neutron imaging; however, the technique remains useful for detecting the presence of other materials, such as organic residues or restoration treatments (Rant et al. 2006, 8).

Archaeologists and conservators may find it difficult to locate a suitable neutron imaging facility. Naturally, such facilities require a neutron source and, as a result, have typically been associated with nuclear reactors. These facilities are few and far between, especially when contrasted against the ubiquity of the X-ray

Figure 3 Photograph and neutron image of an iron bead (Petrie Museum UC10740).

machine. A significant issue for conservators is the transportation of often fragile objects to a distant imaging facility.

State of the field and future developments

The digital revolution has had a significant impact on neutron imaging. The first neutron images were created using photographic film; however, charged-couple device (CCD) cameras are now widely used to produce digital neutron images. The digitization of these images has enhanced the quantitative powers of their analysis: grey values can be quantified and pixels counted. Image resolution is also being improved—the development of increasingly sensitive detectors with large fields of view means that better images can be produced while using a beam of the same intensity (Krejci et al. 2016).

Neutron imaging facilities remain relatively scarce, but are steadily growing in number. The United States has five facilities, while the United Kingdom has just one—the ISIS facility at the Rutherford Appleton Laboratory in Didcot, near Oxford. There are other facilities scattered elsewhere in Europe: one in France, one in Belgium, four in Germany, two in Switzerland, one in Austria, one in Slovenia, one in Poland, one in Hungary, one in Romania, one in Greece (under construction), one in Norway, one in Portugal. Other countries with facilities are

China, Egypt, Algeria, South Africa, Brazil, Argentina, Morocco, Israel, India, Bangladesh, Thailand, Indonesia, South Korea, Japan, and Australia. The International Society for Neutron Radiology provides up-to-date information on available facilities and organizes conferences and workshops. Freely available instructions are provided for the construction of a simple computed tomography system for basic testing. This still requires access to a neutron source. However, more mobile equipment is being developed (Rant et al. 2006, 8; Arai and Crawford 2009). Therefore the technique continues to become more widely accessible and offers an increasingly precise image analysis.

Photoluminescence of Egyptian Blue

GIACOMO CHIARI

Getty Conservation Institute (retired), USA

The synthetic pigment called Egyptian Blue has its counterpart in the natural mineral cuprorivaite, with a formula $\text{CaCuSi}_4\text{O}_{10}$ (Minguzzi 1938). The time and location of EB first synthesis are not known. Corcoran (2016) identified the earliest known example of EB, on a bowl dated to 3250 BCE. The pigment found its larger application in Egypt of the New Kingdom and the Fifteenth dynasty, and subsequently in the Greco-Roman culture where it was used extensively on mural paintings, polychrome statues, and was even used for solid mosaic tesserae. If we think of EB as a compound with a definite crystal structure, its composition is perfectly defined and the ratio between its components corresponds to the stoichiometric formula. The X-ray refinements of a modern synthesized crystal and one found in a Roman archaeological excavation in Aosta are identical within a standard deviation (Mirti et al. 1995). If, on the other hand, we consider EB as the pigment in its complexity as it is used, we may find substantial differences from one case to another, mainly due to the only approximate stoichiometry of the mixes (silica, lime and copper) originally used. Since the silica fraction tends to be in excess, a glass phase is almost always present in the form of the so-called Egyptian Green. The raw materials are also different from place to place, including copper mineral, copper slags or bronze scrapings (in this case, the presence of tin or lead can be the marker). EB was also used in Egypt to make small molded statues or amulets by sintering the fine powder in a mold at high temperature. It is commonly believed that the technology of EB was lost in Western Europe after the fall of the Roman Empire. However, sporadic findings, one dating to the twelfth century (a Last Judgment by Nicolaus Joannes in the Vatican Museum) and a Madonna by Giovanni

Benvenuto dating from 1524 (Bredal-Jørgensen 2011), among others, suggest that somewhere its production continued.

The luminescence of EB is so strong that recently it has found an application in forensic science to detect fingerprints. Discovered in 1996, this luminescence was exploited with success by Giovanni Verri in 2006, who set up the first equipment for imaging EB. A single very small crystal of the order of a few microns can easily be visualized using the technique of visible induced luminescence (VIL). Therefore, in the case that there is some doubt in the attribution of a marble statue to the Greco-Roman period or to the Renaissance, the finding by VIL of a few EB crystals not visible to the naked eye may indicate that the art object belongs to the older period. Future research is certain to expand the temporal range of EB, both by looking for earlier applications and by documenting its use in later paintings throughout Europe.

The VIL technique and equipment

EB is blue in reflected visible light, and therefore has its maximum absorption in the red region, at 637 nm as measured by Accorsi et al. (2009). It reemits energy by luminescence at 910 nm. VIL imaging consists of picking the luminescence signal in the near infrared, having removed all possible interferences. For this purpose digital cameras are used, equipped with a charge coupled device (CCD) obviously sensitive to all visible light (they are built for this purpose). Normal cameras have a short-pass filter in front of the CCDs that cuts out the undesired IR radiation in regular photography. That filter needs to be removed for VIL applications, and specialized photography stores can do this for a fee. On the Internet there are also detailed descriptions of how to reach that filter, if one wants to be brave. Once the IR radiation can reach the CCD, the problem remains of eliminating visible light, which is orders of magnitude more intense than the VIL signal. The solution consists of screening

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0453

the CCD with a long-pass filter that cuts out the visible light but lets the IR signal go through. An appropriate filter should have the absorption edge around 830 nm. Once visible light is eliminated, the further problem remains that some IR radiation may be present in the environment and reflected by the object under examination. In order to capture the VIL signal as clearly as possible, so that it can be attributed to EB luminescence only, one needs to eliminate as much as possible the parasite IR. This IR radiation may be generated by the light source used for the excitation, or be part of the environment. This problem can be solved in two ways, both routinely applied: (1) by eliminating or reducing the effect of the environmental IR, for example by operating in a dark room; (2) by strongly increasing the VIL signal compared with the background, using a much more powerful excitation source. In a studio environment where no ambient IR is present, a source without an IR component (e.g., LEDs of various wavelengths) can be selected, favoring the red ones because of maximum absorption. In the case of sources containing IR, this can be filtered away using short-pass filters (750 nm being appropriate). For the environmental IR pollution the problem cannot be solved using filters, since the wavelength of the VIL signal and that of the light reflected by the object are in the same range. However, VIL may not always be carried out in a dark room, as often there is the need to image non-movable objects in daylight. In this case, increasing the excitation power by using, for example, camera flashes properly filtered to remove the IR component is an adopted solution. The stronger excitation increases the VIL signal-to-background ratio, thus making it possible to perform a proper VIL. The excitation depends on the power of the source and on the inverse square of the distance from the object. It is therefore useful to use more than one synchronized flash and to locate them as close as possible to the object under examination. If one needs to image a large surface in daylight, the use of more than one flash is mandatory. Obviously the IR radiation reflected by the environment is still present, and even parts of the object that do not contain EB show a faint ghost image. This can be dealt with in the image post-treatment.

Images post-treatment

VIL images that show only EB luminescence are rare, being those obtained in a dark studio room using an excitation source totally absent of IR radiation. In the majority of cases VIL imaging is carried out in museums, archaeological sites, or in general in the presence of IR light (see Figures 1 and 2 for examples). This is reflected by the object and cannot be filtered out since it is very similar to the VIL signal. Normally this is dealt with by inserting a non-emitting standard in the image field (but the parts of the object not containing EB can be effectively used as a standard), together with a VIL-emitting standard (normally homemade objects containing EB in various concentrations). Many image-treating programs are available to transpose the image in black and white and then, using the histogram function or the combination of brightness and contrast, evidence the VIL signal. It is highly advisable to take a visible image of the object exactly from the same spot as the VIL one, using a similar camera and the same focal length to avoid distortions. The two images can then be rectified and perfectly superposed and even cross-faded. This series of operations is particularly useful when the amount of EB is small and therefore it is not easy to establish exactly where it is located. The final image so obtained can be effectively compared with other images of the same object, such as by radiography, electron emission, UV and other multispectral images, or the IR image. This exercise gives a large amount of information for the piece of art under examination.

The advantage of VIL with respect to other types of imaging is that VIL is the most sensitive and specific for EB. Although obviously it is always useful to perform other non-invasive analyses as a verification, VIL may not require it. The IR signal penetrates through various types of patinas, including dirt and deteriorated varnishes, thus detecting EB even when it is not visible at all. This was very useful in reading painted inscriptions on sarcophagi that were completely obliterated by the overlying material. In certain instances, EB is mixed with other pigments in order to produce different colors. In these cases, VIL is useful in detecting EB even

Figure 1 (a) Visible and (b) VIL images of a small section of wall painting from the Casa degli Augustali in Herculaneum. Notice the use of adding EB to the white to make it appear brighter. Many more details of the decoration are detectable in the VIL image. Photos: G. Chiari.

when the color of the surface is totally different from blue. We now know that the majority of ancient statues were polychrome, but the predilection for white surfaces on marble statues in the past centuries and the consequent zeal in thoroughly cleaning them have left hardly any trace of pigments. Even a few crystals of EB can prove the presence of an ancient polychromy and thus is useful in authenticating an object.

In conclusion, the ability to exploit the peculiar luminescence of EB when excited by visible light gives conservation scientists an extremely

powerful imaging technique which has found valid applications in several domains of heritage investigation.

Pigment Alteration

AUSTIN NEVIN

Istituto di Fotonica e Nanotecnologie–Consiglio Nazionale delle Ricerche, Italy

Pigment alteration occurs following a chemical reaction or a physical phase change which often, but not always, changes the color of the pigment. While there are many chemical reactions that can occur among pigments, the environment, and binding media, the term pigment alteration refers to a physical change in the appearance of the pigment. There are many different causes for pigment alteration, and some pigments are inherently less chemically stable and more prone to chemical modifications than others: Only a few inert pigments exist. Indeed, the conservation of polychrome and archaeological surfaces (see CONSERVATION OF POLYCHROME NATURAL AND ARCHITECTURAL SURFACES) often involves the documentation and study of pigment alteration, a major challenge for conservation science (see CONSERVATION SCIENCE). The environment and the combined effects of relative humidity, temperature, radiation, and air pollution (see AIR POLLUTION) play major roles in pigment alteration.

Pigment sensitivity to light and heat is attested by historical treatises, but the chemical modifications that are responsible for pigment alteration are the current focus of advanced analytical chemistry: Pliny the Elder in *Natural History* warns of the instability of vermilion (αHgS) to light and its tendency to darken, and Vitruvius in *The Ten Books on Architecture* infers the heat sensitivity of lead white (basic lead carbonate, $2\text{PbCO}_3 \cdot \text{Pb(OH)}_2$). Other treatises describe the darkening of pigments which may occur if they are applied in inappropriate media; for example, Cennino Cennini in his *Book of Art* warns against the use of red lead and lead white, neither of which can be used in fresco painting as they will darken in the alkaline lime medium. The darkening of vermilion and lead-based pigments is easily

recognized by eye, so this type of deterioration is often used to identify their presence.

Given specific chemical conditions (including environmental pollution, exposure to heat, visible and ultraviolet radiation, environmental pollution, and reactive ions of chlorine and sulfur), most pigments can degrade and alter in color. Research has also demonstrated how relative humidity and the role of the binding medium in a paint layer can play a crucial role in the stability of pigments (Saunders and Kirby 2004).

Evidence of pigment alteration

There are numerous documented cases of pigment alteration on wall paintings and the deterioration of polychromy, paintings and monuments, excavated sites and artifacts, and some examples are given in the text below. Wall paintings are particularly susceptible to alteration due to their constant interaction with the environment.

Heat-induced pigment alteration is common and many pigments will change color following firing: Indeed, a bright red pigment can be produced by burning yellow ochre. Heat-induced changes to pigments based on iron oxides leads to the modification of their color. Yellow ochre pigments (based on the mineral goethite, $\alpha\text{-FeOOH}$) alter to red hematite $\alpha\text{-Fe}_2\text{O}_3$ if heated above 300°C . The blue pigment azurite $\text{Cu}_3(\text{CO}_3)_2(\text{OH})_2$ and the green mineral malachite $2\text{CuCO}_3 \cdot \text{Cu(OH)}_2$ react to form the black CuO (tenorite).

Cases of fire damage and subsequent pigment alteration have been reported both for excavated sites and for wall paintings. For example, fires in the Minoan site Phaistos (Crete, Greece) are responsible for the change in the color of the walls of the palace. The altered ochre pigments of the buried Emperor Qin Shi Huang's Terracotta Sculptures (Xi'an, China) have been ascribed to the looting and burning of the tomb shortly after its construction in 209–210 BCE (Blänsdorf and Yin 2006). Fires lit within caves on the Silk Road in the Mogao grottos have also provoked

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0457

different pigment alterations; white pigments based on basic lead carbonate $2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2$ have reacted to form the brown lead dioxide (plattnerite, PbO_2). In other cases, red lead (Pb_3O_4) may either degrade to form the white pigment cerussite (lead carbonate, PbCO_3) or darken to PbO_2 (Yang et al. 2016). Due to their heat sensitivity, the Romanesque wall paintings from the Chapter House in Sigena (1196–1208) appear monochromatic: the paintings were in a church which was burned in 1936.

While temperature-induced alterations are common, other chemical reactions may occur due to the combined effects of high relative humidity, biological activity, and light exposure. For example, paintings by the Italian Cimabue in the Basilica of Saint Francis of Assisi (Assisi) in 1280 present one of the most famous cases of lead-based white and red alteration on wall paintings: the faces and bodies of many of the figures once painted in highlights are now dark brown, ascribed to the formation of plattnerite.

Light-induced alterations of pigments and dyes may result in fading (for example bleaching or photo-oxidation of indigo and other dyes (see MICROCHEMICAL TESTS IN CONSERVATION)). Red lake pigments which are formed following the precipitation of a dye and a mordant are well known to oxidize and lose their color following exposure to light. Oxidation is particularly problematic for unstable modern lake pigments including eosine or Geranium Lake, and Brazilwood (see DYES). Light exposure can also result in a change in color for inorganic or mineral pigments. For example, realgar (orange) which may alter to form χ -realgar and pararealgar (pale yellow) and examples of alteration of the pigment are common in Egyptian artifacts and works on papyrus (Daniels and Leach 2004). The photosensitivity of HgS has been linked to the presence of Cl^- impurities in the natural mineral (see CHARACTERIZATION OF CERAMICS), and recent work has highlighted multiple mechanisms for degradation of the pigment including photoactivation and the presence of elemental Hg as a by-product of chemical reactions which may cause the darkening of the pigment (Da Pieve et al. 2013; Neiman et al. 2015). Other cases of color alteration include the darkening of the modern pigment chrome yellow which is particularly sensitive to visible light. Research

has demonstrated how the coordination and oxidation of chromium may change and cause a darkening of the pigment, as documented in paintings by Vincent van Gogh and other Post-Impressionists (Monico et al. 2013).

Another important mechanism for pigment alteration is the reaction of pigments with ions that include the formation of oxalates through oxalic acid attack (leading, for example, to the formation of calcium oxalate and copper oxalate), or the formation of sulfates and other sulfur-based pigments, for example the conversion of calcium carbonate to gypsum, or the alteration of lead white to galena (PbS). Chloride ions can also attack many metal oxides, sulfides, and carbonates. For example, the red pigment α -HgS (synthetic vermilion or the mineral cinnabar) has been shown to react with atmospheric Cl^- to form calomel (Hg_2Cl_2) a gray-white pigment, while α -HgS can also undergo a phase modification to β -HgS (metacinnabar), turning black (Nöller 2013). An example of a coordination change which may result in loss of color is smalt—a synthetic blue potash silicate pigment containing cobalt which is well known for its propensity to fade following a change from tetrahedral to octahedral coordination of the trapped Co^{2+} ions (Robinet et al. 2011).

Chloride-based compounds are well-known corrosion products on metal artifacts and may also be associated with the alteration of copper-based carbonate pigments such as azurite (blue) and malachite (green), which react to form atacamite and paratacamite ($\text{Cu}_2\text{Cl}(\text{OH})_3$) (Dei et al. 1998). In other cases, lead white may react to form white alteration products (including lead chlorides, sulfates, and oxalate) (Kotulanová et al. 2009).

The reaction between pigment and binding media may cause the formation of complexes and even the formation of soluble or slightly soluble metal soaps, which has been a major focus of research since the 1990s (see PIGMENTS AND BINDERS). For example, zinc- and lead-based carboxylates are commonly found in twentieth-century paint formulations, either as additives to paint formulae or because carboxylates form as a degradation reaction between fatty acids in binding media and the alkaline pigment. The role of carboxylates in the conservation of

easel paintings is of significant concern and a major area of future research.

Measuring pigment alteration

The detection of pigment alteration, causing a color change, can often be made by the naked eye, but analysis is usually required to confirm degradation products and phase transformations or to monitor the distribution, oxidation state, and mechanisms of pigment alteration. Many advances have been made in understanding the complexity of pigment deterioration and the resulting pigment alteration on the micrometric scale using combinations of microscopy and spectroscopy (Neiman, Balonis, and Kakoulli 2015).

The analysis of color change using analytical imaging and reflectance measurements can provide immediate evidence of pigment alteration, and fiber optic reflectance spectroscopy is one of the most common methods for documenting or monitoring deterioration. Colorimetric spaces may be used to measure change difference in chromatic values which may be related to darkening, lightening, or a modification of a pigment hue. Optical microscopy (see OPTICAL MICROSCOPY) and the observation of cross-sections with scanning electron microscopy (see SCANNING ELECTRON MICROSCOPY) is central to the study of pigment alteration, but is usually combined with other analytical methods for the identification of degradation products and the elucidation of degradation mechanisms. For example, X-ray diffraction (see XRD AND MATERIALS ANALYSIS) (XRD) is sensitive to changes in the chemistry of crystalline phases of pigments and has been widely used to follow degradation; most recently, analysis with a microscopic scale resolution has allowed the mapping of pigment alteration to specific layers of paint cross-sections through the use of synchrotron-based microanalysis (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS) (Da Pieve et al. 2013). On the micrometric scale, the oxidation state of pigments and the coordination of atoms studied by X-ray absorption near edge structure (XANES) (see X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS,

XANES)) and their crystal structure with XRD (see XRD AND MATERIALS ANALYSIS) together with molecular spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) have been critical in the study of the degradation of many pigments including smalt, chrome yellow, vermillion, and cadmium-based pigment (Robinet et al. 2011; Monico et al. 2013; Nieman et al. 2015).

There are no universal techniques for detecting and studying pigment alteration, due to the complexity of paint and the unanswered questions regarding the role of the binding media on the instability of pigments, and the interactions that may develop between different pigments in the same or in adjacent pigment layers. Migration of degradation products through paint and the accumulation of alteration products on the surface of paintings are of current interest. Although it is chemically possible to reverse color change in some cases, it would be unethical to treat them (see ETHICS IN CONSERVATION). Research continues to focus on the role of the environment on deterioration, complex interactions between binders and pigments and the formation of carboxylates or metal soaps, and the degree to which pigment alteration can be prevented.

Polymers in Conservation

CHRIS McGLINCHEY
Museum of Modern Art, USA

A wide range of polymers are used in conservation for three main purposes: as adhesives, consolidants, and surface coatings (varnish). Currently used materials with a history of application in the field have been listed along with their general properties (Horie 2010), detailed aging properties, and applications (Down 2015). Their use in conservation dates back to the profession's earliest days, starting with biopolymers, and traces their chemical modification in the nineteenth century and into the early twentieth when synthetic polymers were first commercially available. All three types—natural, semisynthetic, and synthetic—are actively used by conservators in an effective manner. Their intrinsic properties and economic feasibility also account for their use in commercial applications demanding much larger quantities. The impetus for making specific polymers is typically driven by these larger markets which can shift and, for any number of reasons, jeopardize their future availability. It therefore becomes important for the conservator to understand the relationship between polymer structure and some basic approaches to their assessment of key parameters so they can source a new material if necessary.

Polymeric structures typically have hundreds or more subgroups chemically bonded together with the same covalent bonds that hold the atoms within the subgroup together. For example, polyvinyl acetate can be illustrated as $(\text{CH}_2\text{-CHR})_n$, where R represents an acetate functional group attached to the vinyl group repeating n number of times. Polymer viscous and elastic (viscoelastic) properties manifest themselves at a molecular weight above approximately 10,000. The terms “polymer” and “resin” are sometimes used interchangeably, but resins, by contrast, are smaller molecules and have a molecular weight in the range of 500–1,000 (Horie 2010, 241–259).

Resins are sometimes referred to as oligomers (*oligo* meaning several). Like polymers, there are both natural and synthetic resins, but, in contrast, they are not as strong mechanically and may be tacky at room temperature. Waxes are a third class of materials of both synthetic (Horie 2010, 127) and natural (Mills and White 1994) origin, with an intermediate range of molecular weight. They are semicrystalline materials that have poor cohesive strength but function as matting agent additives in varnishes and control the heat set properties of heat-activated adhesive formulations. Some natural resins have a small polymeric fraction that researchers believe influences the handling properties of varnish surface coatings as solvent evaporates and the solute (solids) concentrate (de la Rie 1987). These two groupings—polymers and resins—offer a host of different intrinsic properties.

The structural protein collagen is a biopolymer-based glue with high molecular weight and strong cohesive strength. It has a long tradition of use in the assembly of wooden objects and remains an important conservation adhesive. Collagen glue is derived from helices of three intertwined polypeptides that when heated in water uncoil to form a highly viscous solution. Upon cooling it is impossible for the native helical structure to reform exactly as it was, and instead a three-dimensional network of smaller helical structures bridging more disordered phases is formed. These helical interconnections act as physical crosslinks that can be reversed in a heated aqueous solution. Collagen-based hide glues are characterized by two factors: open working time and strength. “Cold set”-type glues give the longest open working time, permitting the assembly of complex objects, and they have been discovered at archaeological sites along the Silk Road (Chamberlain et al. 2011). The strength of the glue is measured by its gel strength, a parameter related to weight in grams required to displace a plunger resting on a gel of fixed concentration under fixed conditions. Collagen-based glues remain water sensitive and subject to biodeterioration.

Starch, a plant-based polysaccharide responsible for energy storage, consists of a mixture of two biopolymers: amylose and amylopectin. Despite amylopectin having much higher molecular weight, its relative weakness is attributed to the polymers' randomly oriented (amorphous) structure. This amorphous structure also accounts for its solubility in cold water allowing for its separation from amylose. Generally, the strength of a starch paste adhesive depends upon the ratio of amylose to amylopectin and can be controlled by the source of the starch, as well as the extraction procedure for treating the starch granules. It is readily used in paper conservation because it is strong enough for most repairs and easily reversed; it can also be prepared in a variety of different ways. A weaker, less tacky starch-based adhesive is obtained when the starch is fermented: This material, common in Japan, is called furu-nori and thought to be flexible, though that claim has been disproven (Daniels 1988). Using a similar fermentation process, the polysaccharide adhesive from seaweed mucilage, called funori, can be made in a variety of ways. It can be used effectively as both an adhesive and consolidant for matt paint. Like collagen, polysaccharides are problematic for water-sensitive materials.

The structural polysaccharide cellulose has been a focus of early research in polymers before the structure of polymers was known. Cellulose, a plant-based high molecular weight biopolymer, is of little practical use as a conservation material (except in a supporting role as filter paper), but can be chemically modified to render it into a product soluble in solvents practical for conservation. The conversion to a potentially soluble material is achieved by a reduction in molecular weight and an increased functionality on the anhydroglucose unit via chemical industrial processing. A variety of industries use chemically modified cellulose esters (both organic and inorganic) for niche applications, while cellulose ethers are used as thickeners in many different markets. In conservation, cellulose ethers have been determined to weaken by virtue of chain scission degradation (Feller and Wilt 1990). However, they remain important materials effective for treating a variety of different media. Cellulose acetate and cellulose nitrate esters were at one time used in conservation and in particular

fieldwork where rapid drying is useful. However, both are known to degrade by discoloring and release acidic vapor. Water sensitivity needs to be evaluated for these classes of compounds on a case-by-case basis.

Synthetic polymers were quickly evaluated by practicing conservators as soon as their potential was fully elucidated and accepted by the scientific community in the mid to late 1920s. At Harvard's Fogg Museum, Gettens and Stout began testing synthetic polymers in 1929 as a consolidant for wall paintings and found them promising. Many different classes exist and some are formulated to be delivered as solutions, while others are specifically made for dispersions. The distinction is important: The viscosity of solutions is dependent upon molecular weight and concentration, while with dispersions, viscosity is primarily dependent upon thickeners in the aqueous phase often stabilized at a low pH. Polyvinyl acetates (PVAc), for example, exist as both solutions and dispersions (Horie 2010, 137–142). Dispersions have much higher molecular weight and produce durable films when dry—qualities ideal for many commercial paints and some, but not all, conservation applications. PVAc dispersions are difficult to resolubilize and typically only swell slightly and require mechanical removal, whereas solution-based PVAc acts as a viscoelastic solution. Solution-delivered PVAc comes in a variety of molecular weights, with the lowest most at risk of being too soft at room temperature. Oligomeric resins involving different chemistry, by contrast, are most easily removed because their lowest molecular weight of all makes them amenable to dissolving. They tend to have highly branched structures, which helps make them solid at room temperature. While most of the synthetic polymers and resins used in conservation are reversible in isolation, actual reversibility must be considered in the context of the treatment. This level of discrimination will narrow the field of the most suitable material for a given treatment.

Polymers can also include two monomers combined and fit the $(\text{CH}_2\text{-CAB})_x(\text{CH}_2\text{-CRS})_y$ description offering hybrid properties. Such materials are called copolymers. Some of the most commonly used conservation polymers are copolymers. Ethylene vinyl acetate (EVA) copolymers are important components to heat set adhesives used in conservation: The

waxy component of the polyethylene phase covalently linked to the polyvinyl acetate combines good melting properties with high cohesive strength (Ploeger, McGlinchey, and de la Rie 2016). Polyethyl methacrylate poly methacrylate (EMA-MA) copolymers are tough solids with solubility properties that tend to be acceptable for conservation applications. Polymers with three separate repeat groups are known as terpolymers; one example used in some areas of conservation is the so-called butyrls. These polymers contain vinyl acetate, vinyl alcohol, and vinyl butyral. They generally act as deep-penetrating consolidants for bone (Kres and Lovell 1995) and wood (Baker and Grattan 2011), though under extreme aging conditions they degrade and may cross-link (Horie 2010, 146).

All polymer systems described above dry by evaporation of some liquid—whether it is water or some organic solvent. Synthetic polymers fitting this description are considered thermoplastics, meaning they can be melted upon moderate heat treatment and solidified any number of times. That ideal is limited by oxidation or other chemical degradative processes.

Polymers that consist of long chains where any two distant atoms on the molecule can be traced via covalent linkages are classified as thermoset polymers. The entire mass can be visualized as a single molecule which will not liquefy with the application of heat but will eventually degrade at some elevated temperature. Such materials are insoluble regardless of the solvent once they are cured. However, like dispersions, some do swell slightly in specific solvents. This makes them unacceptable for many conservation applications, but there may be some instances where they are needed. Epoxies are examples of thermosetting materials that are sometimes used in conservation because they have excellent load-bearing properties. These systems may be suitable for certain nonporous surfaces, but epoxy cure is rather indiscriminant and will chemically cross-link to plant fibers and many polymers, making them inseparable and thus irreversible. When epoxies are needed for load-bearing applications, a thermoplastic barrier coating can at least prevent chemical bonding to the object, but remains technically difficult to reverse (Podany 2001).

Preventive Conservation in Archaeological Sites

JANE HENDERSON and
ASHLEY M. LINGLE
Cardiff University, UK

Introduction

Preventive conservation is the act of preventing future loss and most definitions exclude actions that interfere with the structure and materials of the item. For archaeological sites, this definition is tested. Preventive conservation measures on finds and samples may primarily involve providing protective enclosures or preserving data, whereas preventive conservation for sites may involve installing temporary or permanent structures or making adaptations to context.

Preventive conservation in archaeological sites can be conceived of as the management of risks. Risk management aims to minimize negative consequences such as uncontrolled loss, while delivering maximum positive outcomes, such as preserving evidence or enabling access. Preventive conservation in archaeological sites should be part of the normal planning process and should be considered from the planning phase forward. This differs from conservation which intervenes in finds or features to uncover additional data or to extend the use of the material, such as micro-excavation of pots, the removal of corrosion, or the consolidation of structures (see CONSERVATION).

Preventive planning

Preventive conservation is a cyclical process. Key actions should be carried out before, during, and after excavation. Each stage should be reviewed and adapted as projects progress. Early planning facilitates the timely inclusion of preventive measures—for example, risk management,

monitoring, protective shelters, creating buffer zones, documentation, emergency preparedness, and visitor management. A multidisciplinary approach allows for the effective implementation of preventive measures, including prioritization of activities and funding. Initial activities are the creation of significance statements and identification of risks to the site and artifacts, leading to risk management strategies that can be integrated into the site management plan. Planning should include a review of relevant local and international legislation, standards, and charters. For sites revealing tangible structures, a conservation management plan should be developed, setting out strategies and resources for the long-term care and use of the archaeological site.

Significance assessment

Significance assessment for finds or samples may be as simple as establishing the research aims of the site and understanding how the sample contributes to them. Alternatively, this may be a complex process of understanding the nature of the site and associated beliefs. For excavators working outside of their own cultural expertise, this process will require significant effort to consider values in terms and formats that may be unfamiliar. Identifying stakeholders such as cultural representatives, land users, community leaders, and other interested parties may be necessary. It is possible for archaeological sites to have multiple and contested associations, posing challenges for preventive conservation strategies. A western scientific perspective may encourage a presumption that tangible material aspects of a site take predominance, but this cultural bias should be scrutinized to consider preserving patterns of ongoing use and interaction. It could reasonably be argued that removing an item from site represents a loss in intangible value, whereas leaving it in situ may threaten tangible aspects. Therefore, the implications of significance assessment should be addressed and revisited throughout the excavation and management of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0476

an archaeological site, to achieve balanced and informed preventive conservation practice.

Risk management

Preventive conservation strategies for archaeological sites require a risk awareness (see *DETERIORATION*) exercise to identify threats to both moveable and immovable features, followed by an assessment of their likelihood and impact, leading to a prioritized action list for risk mitigation. In considering the threats, the tangible and intangible values of the site must be assessed to ensure that both the material substance and the associated values are afforded protection compatible with future use (Paolini et al. 2012). In delivering preventive conservation strategies, a number of risks may be mitigated by the same remedial action; for example, a simple shelter may protect from rain, water, and sunlight.

In order to manage preventive conservation resources, it is necessary to collect data regarding the scale, impact, and likelihood of threats. For some risks this will involve the collection of environmental monitoring data on agents of deterioration, such as relative humidity and temperature. For other risks this will involve factors such as sociopolitical threat or an assessment of geological features.

Preventive conservation by documentation

In some cases, preventive conservation will aim to preserve evidence through documentation (see *CONSERVATION DOCUMENTATION*), from simple analog techniques of listing through photography, to advanced digital methods. Qualitative and quantitative documentation strategies can identify issues such as accelerated rates of deterioration or the efficacy of previous conservation interventions. Recording tools such as photogrammetry, terrestrial laser scanning, and augmented reality are useful in recording the archaeological process or in monitoring the deterioration of the in-situ archaeology. With recent politically motivated destruction, virtual reconstruction has been offered as a solution,

such as the virtual reconstruction of the Bamiyan Buddhas in Afghanistan. Crowd-sourcing techniques can contribute to data monitoring or recovering evidence of lost archaeological sites.

Changes in the depositional environment

Once exposed by excavation, archaeological materials undergo a rapid process of deterioration (Pedeli, Pulga, and Risser 2013). The archaeology that remains to be discovered has reached near equilibrium with its surroundings, slowing the rate of deterioration sufficiently to preserve evidence of its original form, albeit altered by the decay. Survival of archaeological evidence will be dependent on the chemical and physical nature of the material and the micro- and macroenvironment in which it is buried (Leuzinger, Sidell, and Williams 2016).

Preventive conservation efforts recognize the role of burial environment in the endurance of materials, and conservators implement measures to either recreate depositional conditions (e.g., by keeping wet organics wet) or compensate for them by conservation intervention. Inorganic materials such as stone and ceramic tend to survive best. The preservation of glass and metal will depend on the burial environment, with stable conditions slowing rates of decay, and sudden changes in microenvironments accelerating decay. The amount of oxygen available in an environment (aerobic or anaerobic) can indicate the scope for organic preservation and the scale of microbial and fungal degradation (Corfield 1996). Extreme conditions such as low oxygen or temperature favor the survival of organic materials and reduce rates of chemical decay such as corrosion. Those extremes are found in environments such as peat bogs (anoxic), ice (low temperature and humidity), or desert (desiccation). For sites in enclosed spaces with a delicate microbial balance, it is important to monitor for changes both during and after excavation.

Environmental monitoring

Preventive conservation at archaeological sites, in particular those with microclimates or extreme

conditions, requires the collection of data on agents of deterioration such as humidity, temperature, or pollution. Fluctuations in climate can contribute to deterioration on both annual and diurnal scales. Sites that experience broad climatic shifts are at risk of damage due to freeze–thaw cycles, whereby mechanical damage is caused in winter or at night. Sites that are enclosed (e.g., caves/tombs/shelters) may limit some agents of deterioration such as light and wind, but are more at risk from the development of condensation (dew point). The introduction of people to a site, changing patterns of use, or the uncovering or removal of features such as stones within a tomb entrance will change environmental conditions and disrupt equilibrium. Ideally, a preventive conservation strategy will collect baseline environmental data preceding any intervention.

Problems arise where soluble salts and other contaminants are present as they react with changes in the environment, leading to deterioration and mechanical stress. Soluble salts deliquesce and crystallize with fluctuations in relative humidity, leading to efflorescence, sub-fluorescence, and cryptofluorescence in porous materials. Repeating cycles of salt crystallization leads to both surface loss and structural failure of contaminated substrates. While some small finds can be treated for salt contamination, salt present within in-situ features can only be mitigated with environmental controls.

Pollution in urban sites can both accelerate deterioration and create aesthetic damage. Changes in land use and climate change may lead to changing trends in environmental conditions, such as the drying of subsoil, more frequent heavy precipitation events, or rising temperatures. These can lead to both minor changes such as mold growth and major ones such as ground movement or the development of fissures. Some data may be available locally: many national and regional agencies collect data such as temperature, humidity, precipitation, and pollution. Where the site is remote, in a country with limited resources, or contains a microclimate, independent monitoring may be required. Equipment to monitor and transmit data has evolved rapidly, allowing the opportunity for remote logging of sites.

Geology and landscape

Monitoring the hydraulic behavior of the depositional environment is an important part of developing successful preventive conservation practice and acts as an early warning of destabilization (Corfield 1996). Changes in patterns of water movement such as diverting or damming rivers can affect the geology for a large area. Sudden changes in conditions such as a shifting water table may generate significant preventive conservation challenges in a cave or *tell* (artificial mound), many miles away. Successful in-situ preservation depends on a critical understanding of how different factors interrelate (Corfield 1996). Good data monitoring will alert site managers to changing conditions that may lead to investigations of changes in land management patterns in the region.

Shelters

Coverings and shelters can be useful tools for preventive conservation. Textiles such as geotextiles, Gortex, Sympatex, and agricultural netting can be useful in aiding stabilization. Shelters provide a barrier to reduce the impact of inclement weather; protection of delicate features and archaeological sections; reduction of light and ultraviolet damage; cover for ongoing excavation work; and can restrict access or theft and be a beneficial alternative to backfilling (Pedeli et al. 2013). Developing a shelter can be a difficult and expensive endeavor and requires planning, taking into account the climate (both in and outside of the structure); plans for future excavation; the physical impact to the existing archaeology and landscape; and maintenance. If built incorrectly, a permanent shelter can lead to the creation of undesirable microclimates, condensation, and water channeling, and impede study and photography, or collapse on to the archaeological substrate. The installation of shelters may itself be damaging to the context. The impact of any shelter should be considered as part of the conservation management plan for the site.

Emergency preparedness

A plan for disaster mitigation and preparedness requires a comprehensive assessment of catastrophic risks to site, occupants, and visitors. Catastrophic events include sudden ecological or geological events, climate change, and severe weather events, illegal activities, and deliberate destruction. Disaster risk reduction strategies should involve local community members and relevant stakeholders, and include awareness-raising and procedural training. Measures should be put into place to facilitate rescue and response.

Site management

Where a site is frequently accessed, visitors can negatively affect the environment, damaging evidence by benign or deliberate means. Site management might recognize the erosion of an earthen feature by walkers, or wear marks caused by patterns of touching or use. These impacts can be managed by the careful manipulation of the environment through landscape features, the creation of alternative routes, strengthening of walk areas, and access restrictions such as the recent changes to Stonehenge. Deliberate damage such as carving of initials, graffiti, or theft will generally require different preventive conservation strategies. Deliberate damage to a site may also occur due to a lack of awareness of the site's significance, a desire to plunder local resources, or a resentment of public use of an area, such as the Noh Mul Maya pyramid in Belize. In these cases, preventive conservation measures may be structural (fences and locked

gates), social (a campaign of local public engagement and support for site management), or legal (the legalization of protection with associated enforced penalty system for damage). UNESCO's World Heritage Site status can be seen as a preventive conservation measure in this context.

Raman Spectroscopy in Conservation

MARCO LEONA

The Metropolitan Museum of Art, USA

Raman spectroscopy is now a fundamental analytical technique in art conservation, in archaeometry, and, in general, in the study of heritage material. Coupled with microscope optics, a Raman spectrometer makes it possible to characterize with high spatial resolution and in a nondestructive way a range of materials such as pigments, dyes, minerals, gems, glass, ceramic glazes, and synthetic polymers. The technique is often used as part of an analytical chain that includes X-ray fluorescence (XRF) spectroscopy, Fourier transform infrared (FTIR) spectroscopy, and scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS). Compared to XRF, which offers only elemental composition information, Raman, a vibrational spectroscopy technique, easily discriminates polymorphs (for instance, anatase and rutile, two forms of the common white pigment titanium dioxide). Compared to FTIR, another vibrational spectroscopy technique, Raman yields different yet complementary information, because of the difference in selection rules for Raman scattering and infrared absorption and for the radically different experimental setup.

The Raman effect, discovered in 1928 by Indian physicist C. V. Raman (who was awarded the Nobel Prize in Physics in 1930 for the discovery), is an inelastic light scattering effect whereby an extremely small fraction of the photons impinging on a sample is scattered with a defined energy loss (or gain): This is commonly called the Raman shift. The energy difference between exciting and scattered radiation corresponds to the energy of a vibrational transition for the substance analyzed. Complex molecules may show an array of shifts, corresponding to all the possible vibrations of the different bonds in the molecule: This is the Raman spectrum.

In practice, when investigating a material by Raman spectroscopy, an extremely bright source such as a laser is focused on the sample with appropriate optics and the backscattered radiation is collected (usually with the same optics, in a 180° geometry), filtered to block the exciting radiation, dispersed into a range of frequencies, and projected onto a high-sensitivity detector (in modern practice a silicon charge-coupled device (CCD)). The resulting intensity versus the Raman shift graph is the Raman spectrum of the material. Raman spectroscopy is a vibrational spectroscopy technique: It is sensitive to the arrangement of atoms in a molecule and to the way molecular bonds vibrate (stretching or bending) when the molecule is excited. Compared to infrared absorption spectroscopy, where vibrational levels are probed directly by measuring the absorption of infrared light by the sample, Raman spectroscopy differs for the basic nature of the phenomenon. Raman scattering occurs when the polarizability of a chemical bond (the ability of the molecule to acquire an instant dipole moment or separation of charges under the influence of an external electromagnetic field) changes between two vibrational states (in the case of bond stretching, for instance, when the molecule is more easily polarized in the excited (stretched) state than in the relaxed state). Infrared absorption occurs when the permanent dipole of a molecule changes as a result of a vibrational transition. These two complementary sets of conditions, called selection rules, define the different molecular characteristics that are highlighted by each experiment. Infrared spectroscopy is more sensitive to the vibration of highly polarized chemical bonds (for instance, the carbonyl bond in organic acids and esters) and Raman spectroscopy is more sensitive to chemical bonds with lower polarization (such as the carbon-carbon bonds in the chain of an organic polymer). The two techniques differ also in how they are carried out experimentally. In FTIR, infrared light in the 2- to 20- μm wavelength range is used, while in Raman spectroscopy, visible or near-infrared light is generally used (488–785 nm, with some instrumentation using also 1064-nm excitation).

The use of visible light makes it possible to couple Raman spectrometers to optical microscopes, achieving great spatial resolution.

Raman spectroscopy was first applied to the analysis of heritage materials in the 1980s (Guineau 1984), yet it is the work of Robin Clark at University College London that definitely established Raman as a valuable technique in art conservation and archaeometry (Bell, Clark, and Gibbs 1997). A typical application of Raman spectroscopy highlighting its key advantages over other analytical techniques is shown in Figure 1.

The large free-blown glass paten is decorated on the underside in a technique called reverse painting. The paint is applied directly to the underside of the glass bowl, starting with the highlights, followed by the paint and metal foils for the figures and the background, and finally the ground layer. Everything is then covered with an opaque wax layer. The pigments are essentially inaccessible for sampling or for non-destructive analysis by techniques such as XRF, sandwiched as they are between the thick (5–7 mm) glass and the opaque wax coating. With an open-architecture Raman microscope equipped with long working distance objectives, it is possible to focus the laser beam through the glass onto

the paint layer and identify the pigments used by the artist. Similar work has been done on portrait miniatures such as Nicholas Hilliard's *Armada Jewel* (Derbyshire and Withnall 1999). Excellent reviews are available describing in great detail the application of Raman spectroscopy to the analysis of heritage material, including paintings and drawings (Centeno 2016), and archaeological artifacts (Bersani and Lottici 2016). In addition to pigments and minerals, materials of interest in conservation and archaeometry that have been successfully investigated by Raman spectroscopy include synthetic pigments (Ropret, Centeno, and Bukovic 2008) and copper corrosion products (Trentelman et al. 1999).

The key limitations of Raman spectroscopy are low sensitivity, a consequence of the relative weakness of the Raman effect, and interference from luminescence. The latter is of particular importance, as many substances of interest in heritage studies can fluoresce under laser excitation: These include not just impurities or degradation products that may be commixed with the analyte of interest, but in some cases, as for natural and synthetic organic colorants, the analytes themselves.

A possible strategy to reduce the interference from fluorescence is to employ long wavelength

Figure 1 Dish with Abraham and Melchizedek, 1498 (Hans of Landshut, German, Landshut, active late fifteenth century). Overall dimensions: 36.9×4.2 cm.

excitation radiation. This is accomplished with near-infrared lasers, typically at 785, 830, and 1064 nm. The first wavelength is the one that is most commonly found on microscope-coupled dispersive Raman spectrometers. It offers significant reduction in fluorescence compared with blue or green wavelengths, but it cannot completely eliminate the fluorescence typical of organic colorants. More recently, 830-nm lasers have become available, and are being incorporated into portable Raman systems. Finally, 1064-nm lasers offer the best performance in terms of reduction or avoidance of fluorescence interference. This excitation wavelength, however, requires substantially different hardware: either interferometer-based spectrometers with germanium diode detectors (Fourier transform Raman spectroscopy) or dispersive spectrometers with indium gallium arsenide (InGaAs) detectors. A spectral library of pigments investigated by Fourier transform Raman has been published by Burgio and Clark (2001).

More recently, an alternative approach to investigate highly fluorescent materials, surface-enhanced Raman spectroscopy (SERS), has found considerable application in art historical, archaeological, and art conservation studies, particularly for the identification of organic colorants. In brief, organic molecules adsorbed on the surface of atomically rough metals such as gold, silver, and copper experience an extremely high increase in their Raman scattering intensity. Surface-enhancement of Raman scattering is caused by a combination of local electromagnetic field enhancement at the surface of a nanoparticle (or, better, at the junction of two or more nanoparticles) and charge-transfer resonance between a metal nanoparticle and adsorbed molecule. The effect has been more properly described as surface-enhanced Raman resonance scattering (SERRS) to highlight both factors. In practice, a molecule adsorbed on the surface of a metallic nanoparticle experiences under laser excitation a much larger electromagnetic field and it may be closer to resonance Raman conditions than in the absence of the metal nanoparticle.

SERS is carried out by adding metal nanoparticles, typically a silver colloid to a sample obtained from the object under examination. As the organic colorant diffuses out of the sample and adsorbs onto the surface of the nanoparticles, its

SERS spectrum can be recorded. While SERS is not a nondestructive technique, the extremely high sensitivity of the method makes it possible to obtain excellent spectra from samples as small as 20 μm in diameter. Recently, alternative approaches to SERS based on the use of silver nanoparticles dispersed in gels to produce the SERS effect directly on the object under examination, without removing a sample, have been tested. Similarly, the use of inkjet print-heads to deliver picoliter droplets of silver colloid to a print or drawing, thus leaving only microscopic residues on the object, has been proposed. Finally, coupling laser ablation to SERS has been shown to increase the sensitivity of the method for the analysis of painting cross-sections, while at the same time achieving spatial resolution in the order of 5–10 μm .

Typical material investigated by SERS include dyed textile fibers, dyed feathers, lake pigments from archaeological objects, drawings, prints, watercolors, paintings, and polychrome objects. All natural dyes of artistic and archaeological interest (such as madder, kermes, cochineal, lac dye, brazilwood, logwood, orchil, weld, fustic, berberin, and safflower) and a number of synthetic dyes (among them magenta, methyl and crystal violet, eosine, erythrosine, safranin, and mauveine) have been characterized by SERS. A comprehensive review of SERS applications in art and archaeology has been published recently (Pozzi and Leona 2016).

Reflectance Transformation Imaging (RTI) in Conservation

CHANDRA L. REEDY
University of Delaware, USA

The RTI technique and variations common in conservation applications

Reflectance transformation imaging (RTI) is a computational photographic method widely used in the conservation laboratories of heritage institutions worldwide. The basic concept of this technique is that, instead of capturing and viewing a single image of an object, the conservator captures a sequence of images of the object. Using computer algorithms, data can be extracted from that sequence of digital images and used to synthesize a new digital representation or type of image. This new image reveals surface information not visible under direct empirical examination of the subject and not visible in any of the original individual images. RTI is based on the polynomial texture mapping (PTM) technique that was first developed at Hewlett Packard Labs (Malzbender, Gelb, and Wolters 2001). Subsequent research has greatly extended heritage applications and led to the development of alternative algorithms for data extraction, including the widely used hemispherical harmonics (HSR) approach (Mudge et al. 2008). The nonprofit organization Cultural Heritage Imaging (CHI) has taken a leading role in research and education in this technique, with extensive outreach to conservation professionals in the United States. CHI provides freely available software and online resources such as a capture guide and instructional videos, as well as equipment kits and periodic workshops, thus enabling conservators to access the technique (<http://culturalheritageimaging.org>).

Most conservators now use the highlight RTI image capture method. In this technique,

multiple images (often 48 or more) are taken with the subject in a fixed position and the camera remaining stationary on a tripod, while the light source is moved from point to point in the shape of a dome around the subject, always maintaining a constant (measured) distance from the subject (Cosentino 2013). Ambient light is excluded as much as possible, so that the light comes primarily from the strategically placed light positions. Each image in the series will have varying highlights and shadows. One or more black reflective spheres are photographed alongside the subject, reflecting back a lit highlight that the software uses to determine the exact location of the light source for each image in the series. The software needs the known light positions to calculate the “surface normal” of each pixel (i.e., the vector perpendicular to the point where the light touches the surface); these surface normals provide information about 3D morphology of the surface. Since each surface normal connects to a point on the object, the entire series indicates the topography. An alternative to the highlight method is to use a purpose-built dome with a light array permanently installed. This is an efficient system for large throughputs with relatively small subjects, but building such a light array can be expensive. In contrast, the highlight RTI method is low-cost enough to be accessible to even small conservation laboratories, private conservators, or archaeological field conservation laboratories.

The RTI Builder software processes the images (<http://culturalheritageimaging.org/>) using the illumination information gathered from the entire suite of images to generate a mathematical model of the object surface. The software synthesizes the entire image series into a single RTI 2D image that carries 3D information through the combination of shadows and highlights and the surface normal data. The software can calculate this 3D information because the positions of the subject and camera remain fixed, many different light positions are used, and the exact position of the light source can be determined for each image in the series. Two mathematical methods for extracting surface normals are available: the older

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0502

polynomial texture map (PTM); and the newer hemispherical harmonics (HSH) approach. Recent research shows that the latter produces improved 3D rendering (Manfredi et al. 2014).

The RTI Viewer software (<http://culturalheritageimaging.org/>) enables interactive relighting of the subject from any direction and under a variety of filters that improve the contrast between surface details and enhance surface texture. For example, it is possible to remove the color data so surface morphology is the focus. Mathematical enhancement of those morphological features may reveal new information. The surface can be rendered shiny (specular), so that fine surface details are more visible. Conservators can extend the power of RTI even further by combining the technique with infrared or ultraviolet light, or by using it under a microscope.

Qualitative RTI in conservation

The ability to increase the amount of surface information visible is a clear advantage for many conservation tasks. Standard photographic techniques often do not adequately document all the details of the surface texture of an object. The enhanced surface detail available with RTI can often allow conservators to discern evidence of fabrication or manufacturing methods that can help identify an artist or a period, place, or technique of production (see Figure 1).

For example, Artal-Isbrand and Klausmeyer (2013) used RTI to answer questions regarding tools, craft techniques, and production sequences used by Greek red-figure vase painters. Topographical features of painted ceramics, such as preliminary sketch lines, broad contour lines surrounding figures, and relief lines used to outline figures and to indicate shapes such as ears and eyes, were more clearly discernible with RTI than with other photographic techniques. The RTI examination also provided insights into the production sequence used by the painters, by revealing the order in which each step was executed.

The enhanced surface details produced through RTI also enable conservators to conduct more thorough condition assessments, provide stronger condition documentation, and analyze better the effects of conservation treatments (see Figure 2). For example, experiments show that

Figure 1 Song dynasty green-glazed shard from Sichuan Province, China: shown in raking light (a) by comparison with RTI specular enhancement (b), both with overall view (1) and a close-up view (2). The crack patterns in the glaze are an important technical feature in Chinese ceramics, and these details are more clearly visible in the RTI images. Bubbles in Chinese glazes are often deliberately engineered for optical effects; the many small bubbles here are better defined in the RTI image, which also highlights the presence of small, round, dark spots of concentrated iron oxide colorant.

Source: Author.

RTI is an important aid in the conservation condition assessment and documentation of ancient coins (Kotoula and Kyranoudi 2013). It was found to be very helpful in coin identification, even for very low relief details and for highly corroded coins. It also improved conservation examination and condition-reporting steps by enhancing surface effects such as pitting, scratches, corrosion, surface deposits, and areas

Figure 2 Three lead coupons were artificially aged under exposure to different exhibition and storage materials, each causing differing amounts of corrosion: (a) has essentially no corrosion, and the parallel lines of polishing marks are visible; (b) has some corrosion, obscuring some of the polishing lines; and (c) has severe corrosion and almost no polishing lines remain. Each coupon is shown in raking light (1) by comparison with RTI surface enhancement (2). While the raking light views show some of the corrosion products, these are more visible in the RTI images, as is the surface texture of polishing lines and pitting corrosion.

Source: Author.

of loss, so these could be more fully described and documented. The surface effects of conservation treatments could also be better visualized and monitored.

RTI successfully identified textural features not visible to the eye or through raking light photography on a seventeenth-century watercolor landscape painting on paper support (Manrique Tamayo, Valcarcel Andres, and Osca Pons 2013). These textural features included previously unknown details about the artist's working method. RTI showed that the artist used a hard tool such as a pencil or ink pen to delineate the outlines of buildings and roads. This technique left subtle impressions on the paper that became visible only through RTI. Other textural features related to the preservation condition of the

watercolor were also enhanced by RTI, including wrinkling and other deformations of the paper, joins, and fold marks. In another paper example discussed by the same authors, a colored print from a seventeenth-century book, RTI indicated that that artist had used two different pieces of paper to create a single page. The evidence was that laid lines on the main illustration became visible with RTI, but the rest of the page was lacking those laid lines.

RTI has also been successfully used in paintings conservation. For example, it was applied to the condition assessment of a sixteenth-century oil painting on a wooden support panel (Manrique Tamayo, Valcarcel Andres, and Osca Pons 2013). RTI was helpful in discerning a wide variety of condition

characteristics such as deformation of the wood panel, cracking of paint layers, scratches, areas of paint loss, and cupping. RTI also helped the conservators identify texture or brightness discontinuities that marked the places where repainting or previous cleaning had occurred. The same authors applied RTI to another sixteenth-century oil painting on a wooden panel support in order to monitor and evaluate the success of a conservation treatment. In this case, the painting had endured a fire during the Spanish Civil War of 1936, and this event had resulted in many blisters on the paint surface. The large blisters could be documented through raking light photography, but the small ones (less than 1 mm diameter) could not. RTI was successful at revealing and documenting these very tiny blisters. Monitoring the success of the treatment for consolidating and flattening blisters continued with RTI incorporated into the workflow.

Architectural conservators are now using RTI in an outdoor environment, although adjustments to the capture technique are necessary when one is working outdoors rather than in a dark studio. For example, Gabov and Bevan (2011) demonstrated the utility of RTI in the examination and treatment of weathered sandstone and limestone façades. RTI documented better than standard photographic methods the evidence for production methods, such as original tool marks, and for deterioration features, such as surface spalling. The specular enhancement feature of RTI showed much better than natural-light photography the extent of surface spalling. In the case of Gabov and Bevan's façades, RTI revealed that little of the original surface remains intact. Yet in spite of the surface deterioration, RTI indicated the presence of original letters carved onto the surface of the stone. The details of the photographic setup were meticulously recorded (e.g., the distance of the camera from the object photographed, the height of the camera from the ground, and the dimensions of the object), and the camera was perfectly aligned, either on a vertical or on a horizontal plane. As a result, the RTI process should be repeatable under similar conditions in the future, which is important for conservation documentation and continued condition monitoring. Gabov and Bevan concluded that the improved documentation ability, coupled with the ease of

use and the low cost of the RTI technique, meant that this should be seen as a standard part of the tool kit for recording architectural stone surfaces before and after conservation treatment.

Many conservation research groups are also carrying out ongoing experiments designed to incorporate RTI into other examination and documentation workflows typically found in a conservation laboratory. For example, incorporating infrared photography and ultraviolet photography with RTI extends the capabilities of the technique. It is also possible to incorporate RTI into optical microscopy examination, for microscopic RTI. Kotoula (2015) combined RTI with multispectral imaging, capturing highlight RTI images with a UV-VIS-IR camera, a range of filters, and IR or UV radiation sources. She applied this technique to the study of glazed ceramics and found that this approach provides much information about production methods, condition, and conservation treatment effects. For example, this extended RTI approach revealed evidence of pressure applied by the potter at joins, preparatory drawings under glazes, and the sequence of color applications. The extended RTI also indicated the initiation of salt efflorescence, scratches, areas of missing glaze, microcracks, and tiny blisters in the glaze; and it enhanced the topography of any surface damage or glaze deterioration. It also clarified the presence and morphology of past repairs. Remains of materials that had been applied in past conservation treatment campaigns could be discerned, both on the surface and within repair areas.

Quantitative RTI in conservation

RTI also shows promise beyond interactive relighting of an object from any light direction and the resulting qualitative surface enhancements. The ability to document surface texture in a quantitative manner is crucial for a conservator who needs to analyze changes that occur over time. Examples are the subtle or progressive changes due to inadequate environmental conditions that may be causing deterioration of the object; or changes seen before and after the application of a conservation treatment, whether these are intended goals of the treatment or inadvertent

and unwanted side effects. Quantitative work always requires that the conservator take care to ensure that there is a fully measured, recorded, and repeatable photographic setup. Quantitative RTI has found use in the condition documentation of objects, in measuring and monitoring deterioration, and in assessing the results of conservation treatments. It is also being used in the development and testing of the visual effects of new conservation materials (such as adhesives, protective coatings, cleaning materials and methods, etc.). RTI can help ensure that the proposed new materials or treatment techniques will not negatively impact the appearance of the surface of an object. While quantitative RTI is still a relatively new and emerging technology, useful applications of it have been reported in the conservation of paper, paintings, a variety of museum object types (ceramics, stone, metals, wood, bone, and leather), and outdoor architectural stone.

For example, Manfredi et al. (2014) carried out experiments using a model drawing that they created in order to examine how reproducible and quantifiable RTI can be for measuring surface changes. By monitoring the surface normals over time, it is possible to detect small-scale morphological and physical changes in an object that may be due to exposure to the environment or to a conservation treatment intervention. However, a surface normal for a particular pixel can only be considered changed by the environment (or conservation treatment) if the value exceeds a statistical control (the accidental variation encountered from one RTI session to another). Manfred and colleagues measured the repeatability of computed surface normals by recording all of the image sequences for RTI five times, in five separate imaging sessions. They moved the camera position slightly for each session (to mimic setting up separate photography sessions at different times). They computed the surface normals from these image capture replicate sessions using both the PTM and the HSH methods. The average variability was then calculated. The authors found that, while the PTM method is not repeatable, the HSH method is in fact very reproducible and therefore more sensitive to detecting actual surface changes than is the PTM method.

Manfred et al. (2014) subsequently developed an RTI monitoring protocol using the HSH

method that successfully detected damage they deliberately made to their experimental drawing. They considered change to have occurred only in those pixels that were offset to a greater degree than the statistical limit of variability. They created a map of the changed pixels, to illustrate the changes that occurred to the damaged model drawing. This work demonstrates that RTI can be reproducible and quantifiable enough to be used as a practical method for measuring change over time on the surfaces of cultural heritage objects. Research into improving the accuracy of quantitative RTI is still being made by various groups. This work includes efforts to incorporate the most accurate surface normal calculations possible into the available open-source RTI software tools.

Terahertz Imaging in Conservation

KAORI FUKUNAGA

National Institute of Information and Communications Technology, Japan

Electromagnetic waves are widely used in heritage science in nondestructive testing methods. The penetration depth and spatial resolution depend on the frequency and the test object's physical properties. For example, X-ray radiography reveals the internal structure of an object if it can be placed in the system. X-ray fluorescence (XRF) and ultraviolet and infrared waves are used for material analyses, as well as spectroscopic imaging. In archaeology, microwave radars or ground-penetrating radars (GPR) are also commonly used to investigate objects under the soil. The frequency range between microwaves and infrared (i.e., terahertz or THz waves) is one of the emerging technologies in heritage science. There are several commercially available THz imaging systems that are transportable, and there have been various experimental studies demonstrating the advantages of this frequency range (Jackson et al. 2011).

The frequency of terahertz waves is typically between 0.1 and 10 THz (1 THz = 300 μm , 33.3 cm^{-1} = 4.2 meV, 48 K). In addition to classical THz spectroscopy using a Michelson interferometer (i.e., the far-infrared option of a common FTIR spectrometer), THz time domain spectroscopy (TDS) technology was developed in the 1990s. A THz-TDS system uses a narrow pulse, the width of which is of the order of picoseconds. By applying a fast Fourier transform (FFT) to the transmission pulse in the time domain, spectra in the frequency domain are obtained. Since the energy of THz waves corresponds to weak bonds, THz spectroscopy is expected to be an analysis tool for organic–inorganic composites, including paints. In fact, there was active research on mineral pigments in the 1960s and 1970s during the development of FTIR spectroscopy (Karr and

Kovach 1969). Early attempts to apply THz technology to artworks were aimed at spectroscopic imaging. Although model experiments suggest the possibility of material analyses, reflection signals from real artworks are not sufficiently clear to identify a given substance. Thus, other established methods, such as XRF or IR, are used to clarify experimental data. Since these analytical techniques often require sampling or observing a small area at a given time, it is practically difficult to obtain an entire material map of an artwork. On the other hand, THz imaging can roughly indicate the material distribution in shorter time than XRF, meaning that a THz reflection image can suggest points where precise measurements should be made. For example, a fragment from a wall painting at the Dazhao Monastery in Inner Mongolia, which was previously analyzed by XRF and Raman spectroscopy, was analyzed by THz imaging (Fukunaga et al. 2010). The XRF and Raman spectroscopy data were obtained from points chosen by a researcher's visual inspection. Lead was detected from one point in an orange area; and the orange color in this fragment was determined as minium at that time. The reflectivity of THz waves in this orange area was found to be high. However, THz imaging revealed that there are some orange parts that show low reflectivity. This result suggests that another orange material was also used. Therefore, XRF element mapping was performed to investigate this aspect of the orange color. The orange parts that have high reflectivity in the THz image were painted with a lead-based pigment, which is most likely minium. On the other hand, no specific mineral was found for the orange parts with low reflectivity. As illustrated by this example, THz imaging is a complementary technique for indicating points to be measured by using other well-established measurement methods.

In this decade, many research groups around the world have been actively using THz imaging techniques. Experimental results obtained with different types of objects, such as panel paintings, wall paintings, and archaeological vases, have proved that the THz frequency band

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

has particular advantages in internal structure observation using a THz pulse. Noninvasive cross-section images at the positions of interest and area images at the depths of interest are the biggest benefits. One practical advantage of THz imaging is the ability to detect separation in a multilayered object, because a layer of air between two dielectric materials produces high contrast in the imaging results. Separations occur between supporting materials (e.g., paper, wood, canvas, stone, brick) and preparation layers (e.g., mortar, gesso, clay), or between preparation layers and painting layers. Even if a visible crack on the surface is thin, the separation area underneath could be large. By using THz imaging, conservators can see internal defects and can choose an appropriate technique. In the case of Japanese panel screens made of multilayered pieces of paper, the entire internal structure, such as a glued area or the condition of a calcite preparation layer, can be visualized precisely. Structural information on these light materials is not easily obtained by X-ray radiography in transmission mode. Thanks to the strong reflection from a metal surface, THz imaging can easily detect metallic objects, such as gold leaf, under dielectric materials. For THz experts, this may be too simple to be recognized as an important application of the THz imaging technique. However, it is practically useful for conservators, because a painted area with gold leaf underneath is extremely fragile.

A THz area image is generally obtained by TDS by integrating the reflection pulse sequence at each point during the scanning. An area image can be formed by assigning values at each measurement point, for example, the maximum value as white and the minimum value as black. By extracting a specific reflection pulse in the observation area, the condition of the layer of interest, such as the surface of a supporting material, can be examined. Thus THz imaging can be used to analyze a painting as if it has been sliced layer by layer from the surface. Some studies have revealed the condition of a wood surface and the internal defects of panel paintings (Fukunaga and Picollo 2010). In addition to THz-TDS imaging, there are also imaging systems that use continuous waves (CWs), including THz tomography systems, and quasi-real-time imaging systems developed with resonant-tunneling diodes (RTDs) (Miyamoto et al. 2016). Bordeaux University has developed

a THz CW tomography system (THz scanner) using a Gunn diode source operating at 110 GHz. The system has successfully examined the interior of sealed Egyptian vases and found objects inside, which could not be observed by X-ray radiography (Caumes et al. 2011).

The number of THz users in the heritage science field is increasing rapidly, and the first international conference dedicated to the application of THz technology to the examination of art objects was held in 2014—more than 70 people attended. By accumulating case studies and improving signal analyses, THz technology will provide more useful information for conservation science in heritage studies in the near future.

Archaeointensity

FRANCISCO JAVIER PAVÓN-CARRASCO

Universidad Complutense de Madrid, Spain

MIRIAM GÓMEZ-PACCARD

Spanish National Research Council, Spain

Direct measurement of the geomagnetic field intensity has only been available since 1833, when Gauss developed in 1832 an instrument for its measurement. Prior to that epoch, the estimation of past geomagnetic field strength requires the paleomagnetic analysis of rocks and baked archaeological material that carry a remanent magnetization of thermal origin, that is, a thermoremanence. Contrary to the directional geomagnetic elements (declination and inclination), for which measurement protocols in the paleomagnetic laboratories are well established, the archaeointensity determination is more complicated and requires very long experimental times. This is one of the reasons why recent archaeointensity compilations are poorly distributed, both temporally and spatially. Archaeointensity data are key for better understanding the past Earth's magnetic field, since this geomagnetic element is crucial for accurate dipole moment estimations (Valet et al. 2008), that are used to constrain geodynamo numerical models and to reconstruct the past solar activity based on geomagnetically dependent radionuclide records. In addition, the time variation of the past geomagnetic field intensity can potentially be used to date archaeological material or volcanic rocks by means of the archaeomagnetic dating method (see *ARCHAEOMAGNETIC DATING OF BAKED CLAY FEATURES*).

Physical background and archaeointensity measurements

The physical phenomenon behind the archaeointensity measurements is the same as that detailed

for archaeomagnetism (see *ARCHAEOMAGNETISM*). In short, some archaeological materials contain iron oxides, such as magnetite or hematite, that, after heating above the Curie temperature, have the ability to record the direction and strength of the ambient magnetic field present at the moment of cooling. This kind of magnetization is denoted as thermoremanent magnetization (TRM) and is preserved in the material until further heating. These iron oxides can be found in a wide range of archaeological structures (e.g., kilns, furnaces, ovens) because of the clay products used for their construction. Recent studies also suggest that materials from archaeometallurgical context (e.g., slag deposits) are suitable for archaeointensity estimations.

Although the first works on archaeointensity determination were published by Folgheraiter (1899) and Koenigsberger (1938), Thellier and Thellier (1941) were the first scientists to obtain reliable archaeointensity data from bricks and other baked clays. Their experiments were based on the proposal of Folgheraiter (1899) who established that the ratio between the past field intensity and the present field intensity is equal to the ratio between the natural remanent magnetization (NRM) produced by cooling in the past field and the TRM after cooling in the present field; in mathematical terms, $H_{\text{past}}/H_{\text{present}} = \text{NRM}/\text{TRM}$. According to the previous expression, a plot of NRM lost versus partial TRM (pTRM) gained, called the Arai plot, should give a straight line whose gradient is used to determine the archaeointensity data. The associated uncertainty can be determined from the fitting goodness of the slope (by a linear regression). Under this assumption, Thellier and Thellier developed a laboratory protocol, which consists in a double heating-cooling cycle performed in two opposite magnetic fields (Thellier and Thellier 1959). This method, together with the previous Néel's theory (Néel 1949) for the TRM of single domain grains, established the physical bases to understand how an archaeological heated material can be magnetized. As recognized in these works, two fundamental magnetic properties—the grain size of the magnetic

DOI: 10.1002/9781119188230.saseas0024

particles and the shape of the minerals—play a major role in TRM acquisition. Nevertheless, these methods and laws are valid for ideal conditions, and many problems can occur when experiments are performed on natural assemblages containing a wide range of magnetic minerals and grain sizes (Dunlop 2011). The identification of these problems is a major scientific barrier that is challenging the paleomagnetic community at present.

The most common problems, which lead to unsuccessful intensity determinations, are thermally unstable ferromagnetic phases, the presence of coarse (multidomain) grains, and secondary remanent magnetizations. In order to detect these common problems and to check the ability of the specimens to reliably record the ancient geomagnetic field, several different approaches have been used (see Genevey et al. 2008). For example, Coe (1967) modified the Thellier–Thellier method, including a double heating–cooling step performed first in zero field and then in an applied field, becoming nowadays the most common method for archaeointensity determination. Apart from the classical method of Thellier–Thellier and its modifications, other approaches have been developed. Some are based on the NRM demagnetization by alternating magnetic fields; and others on replacing the thermal demagnetization technique with microwave demagnetization during the heating–cooling cycles of the Thellier–Thellier method. The idea of the microwave method is to magnetize and demagnetize the samples without the application of extreme temperatures and, thus, limit the possible mineral alteration. More recently, the multispecimen method has been introduced. This method consists of the heating of a series of sister specimens to a single step of temperature selected according to the blocking temperature. A different field strength is applied to each different sister specimen, and archaeointensities are recovered by determining the field for which the difference between the laboratory pTRM and the ancient TRM, normalized over the ancient TRM, is minimized. One advantage of the multispecimen method is that it is quicker than the classical Thellier–Thellier experiments and it presents a lower risk of magnetic alteration. For a complete review of the different archaeointensity methods

see Genevey et al. (2008) or Dunlop (2011) and references therein.

One of the major weaknesses of the Thellier–Thellier method and its modifications is the mineralogical alteration of the samples during the laboratory protocols. New magnetic phases can appear when Fe-rich materials such as clays, which are rather common in archaeological features, are heated to high temperatures. For this reason, it is a key point to control and test the alteration of the magnetic mineralogy during the experimental procedure. pTRM-check tests, first introduced by Thellier and Thellier (1959), estimate the stability of the TRM and are the most efficient method for detecting magnetic alteration during archaeointensity experiments constraining the reliability of the intensity results. Such tests, however, have not always been performed, especially for data acquired before 1985.

Other important factors that must be taken into account in archaeointensity experiments are the anisotropy of the TRM and the cooling rate dependence of the TRM acquisition. The first effect (denoted as ATRM) can be particularly important for ceramic fragments, tiles, and some other archaeological baked artifacts (e.g., pipes) and reach, in some cases, very high correction factors of more than 70 percent of the determined field strength. In most cases, the ATRM effect is evaluated directly via determination of the TRM anisotropy tensor. An alternative is to adjust the direction of the laboratory field to produce a TRM parallel to the NRM. Other methods can be found in the review paper of Genevey et al. (2008). The second factor, the cooling rate dependence of TRM acquisition with cooling time, can be important when laboratory cooling times (usually of about 1.5 h) are very different to the cooling time of the ancient firing. The cooling rate dependence of TRM intensity can be determined experimentally by measuring additional TRM acquisition steps at different cooling rates. Some authors judge that this correction is unnecessary in their study because the experimental and the original cooling rates are considered similar, and in some laboratory protocols the effect is automatically corrected. However, in the majority of the archaeointensity studies, data are derived from pottery fragments or structures for which the original cooling time is unknown (from an archaeological point of view). The adequate

correction of this effect is, therefore, a major challenge nowadays. In any case, the evaluation of this effect is not made for almost 80 percent of the data of the recent archaeointensity dataset (Genevey et al. 2008).

Present and future challenges

The most recent compilation of archaeointensity data is Geomag50.v3 (Brown et al. 2015). This database contains all the available archaeointensity data for the Holocene together with their corresponding information (such as the laboratory procedure followed to estimate the paleointensities and the associated dating methods and uncertainties). As mentioned previously, the archaeointensity data, along with the directional field, declination, and inclination, present a very inhomogeneous spatial and temporal distribution for the Holocene period (last 12,000 years). About 50 percent of the archaeomagnetic data come from sites with ages between 650 and 1900 CE and only 17 percent of them correspond to ages before 1000 BCE. This percentage is reduced to 2 percent for ages prior to 5000 BCE. The majority of archaeointensity determinations correspond to the northern hemisphere (~96% of the total), with the highest density of data in the European continent. However, great effort is being made to collect data from new areas from the southern hemisphere, such as Central–Southern America, Africa, and Oceania (see Brown et al. 2015 and references therein), where new sets of archaeointensity data are emerging.

In addition to the low number and poor spatial and temporal distribution of data, there is another main problem: the high scatter observed in regional databases, which clearly indicates that some of the data available in the databases might not be reliable, as has been argued in different studies. During the last years, in an effort to obtain a high-resolution description of past geomagnetic field intensity changes at regional scales, different authors applied selection criteria to estimate the reliability of available archaeointensity data. In some of these studies the authors even considered some of the data as unreliable and rejected them in their interpretation of past geomagnetic field variations. This is, perhaps, an extreme point of view, but it underlines the need to develop

robust palaeomagnetic criteria for evaluating the reliability of the intensity estimations contained in the databases before using them for modeling the past variation of the geomagnetic field.

Archaeomagnetic Dating of Baked Clay Features

ELISABETH SCHNEPP

Montanuniversität Leoben, Austria

Basics and principles

When archaeological finds and historical documents do not allow one to establish absolute chronologies, natural science dating methods are needed which provide an age on human timescales. Among others (e.g., radiocarbon, dendrochronology, or thermoluminescence (see THERMOLUMINESCENCE) dating), the archaeomagnetism (see ARCHAEO-MAGNETISM) of baked clay features can be used to do so. The various methods have different advantages and drawbacks, leading to an uncertainty in age which has to be taken into account. In other words, each method provides an interval of age within which the feature dates with a certain probability. One major advantage of archaeomagnetic dating is that in most cases the activity of our ancestors is directly dated. The method needs a calibration curve that is built from archaeomagnetic data obtained from independently well-dated baked clay features. Nevertheless, the method may also be used to establish relative chronologies when data from several features at a site are compared or the trend of the geomagnetic variation is roughly known from global models.

At the Earth's surface the geomagnetic field can roughly be described as the field of a geocentric dipole (very short bar magnet) inclined with respect to the rotation axis. Non-dipole terms are also relevant, and both parts slowly change with time. At a location the geomagnetic field vector is described by three components. The field direction is represented by declination (D), the direction of the magnetic compass relative to geographic North, while inclination (I) is the tilt of the magnetic field line. The field's strength is called intensity (F). When the direction moves, D and I increase or decrease as well as F on

timescales of decades to millennia. This phenomenon is called geomagnetic secular variation. Archaeomagnetic dating of baked clay features can use one, two or three of these components describing the field. Because secular variation does not show a simple trend on timescales of several centuries to millennia, archaeomagnetic dating may be ambiguous, especially when only one magnetic component is used.

Materials and sampling

Although some earlier magnetic investigations on baked clay features exist, Emile and Odette Thellier were the first to gain international recognition for systematic research with the aim of using archaeomagnetism for dating. Regardless of whether accidentally or intentionally exposed to heat of at least several hundred degrees Celsius (best if greater than 600°C), any archaeological feature or find of clay, loam, soil, or rock, in principle, can be used for archaeomagnetic dating. These are in situ features like hearths, any kind of fireplace, ovens, kilns, or furnaces which were used for domestic fires, production of pottery, brick, lime, metal, glass, or such like, as well as layers of burn caused by intense fire. Suitable displaced materials are ceramics like pottery, bricks, tiles, tuyeres, daub, or whorls made of baked clay. While in situ features can provide all three vector components, the archaeomagnetic direction at the site is lost as soon as the material has been displaced after cooling.

Dating usually uses the archaeodirection. This requires oriented samples to be taken from the baked clay feature which remained in situ since its last heating and cooling in the geomagnetic field. Any disturbance (e.g., tilting) would cause an error of the measured archaeomagnetic direction and hence corrupt the dating. Displaced baked clay material like bricks or pottery may allow measurement of the inclination when reasonable assumptions can be made about how they were oriented during the firing process. However, such material is often very suited for determination of the archaeointensity (see ARCHAEOINTENSITY)

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0035

recommended as a second or third parameter for dating. Weakly baked clay is not suited for archaeointensity measurements, but may be used for determination of the direction because it is partially remagnetized.

For determination of archaeodirection, at least 6 but preferably 15–25 independently oriented samples spread over the feature are recommended. Depending on the hardness of the baked clay, they can be taken using different techniques, such as blocks covered with plaster, drill or soft cores, small pieces with an orientation mark glued on it, or plastic containers pushed into the material (e.g., Trapanese, Batt, and Schnepf 2008, and references therein). Apart from geographical coordinates of the site, the orientation of each sample in space is required. This is achieved by applying a fiducial mark (arrow), of which the angle with respect to geographic North and the dip with respect to the horizontal plane are measured before removing the sample. The simplest orientation is installing a horizontal plane on the sample block and marking magnetic North precisely using a compass. More sophisticated techniques require special instruments.

Experimental procedures

While small pieces or plastic containers provide samples that are ready to measure, large samples of unconsolidated baked clay may need consolidation in the laboratory first, before blocks or cores are cut into specimens of usually about 10 cm³ volume. Laboratory procedures may include measurements of rock magnetic parameters for characterization of the magnetic particles. Determination of the so-called characteristic direction of the specimen is essential, since this is a measure of the archaeomagnetic field direction during the last cooling of the feature. The standard procedure is to determine the initial magnetization and to demagnetize it by heating or alternating magnetic fields. The demagnetization series is used to find the characteristic direction with principal components analysis. Demagnetization is necessary because the initial magnetization may have overprints of different origins, or weakly baked clay may only carry

a partial thermoremanent magnetization. All directions are then combined to give a feature mean. It is recommended to calculate this mean archaeomagnetic direction in a hierarchical process by averaging first the results of all specimens at a sample level and then on a feature level (Lanos et al. 2005). This mean direction (D and I) is characterized by three parameters: number of independently oriented samples ($n \geq 5$), confidence circle ($\alpha_{95} \leq 5$), and precision parameter of the Fisher statistics ($k \geq 50$). Well-defined archaeomagnetic directions should respect the limits given in brackets. As α_{95} decreases with increasing n , values of the order of 1° or less can be reached. When only a few samples are measured, a large k (≥ 200) indicates a precise measurement although α_{95} may be as high as several degrees. The archaeomagnetic direction may be accompanied by the archaeointensity which is much more laborious and experimentally difficult to obtain.

Dating

For the dating procedure D, I, and/or F are used for comparing them with appropriate calibration curves for the region. This is done by using software (Pavón-Carrasco et al. 2011; Lanos et al. 2005) that calculates, for example, the overlap of the archaeodirection's confidence circle with the confidence band of the directional calibration curve. Normally the confidence limit is set to 95%, which means that the age of the feature lies with 95% probability within the dating interval provided by the software. Using the archaeointensity as a third parameter can increase the precision of the dating considerably, when a suitable calibration curve is available. The precision of dating is strongly dependent on the time period in question. Similar to the plateau effect of radio-carbon dating, the directional archaeomagnetic calibration curves form cusps or loops in which the direction of the baked clay feature may lie. Then a large age interval will be obtained which can last several hundreds of years. In contrast, the dating error may be pretty small if the direction lies outside the loop or if secular variation was rather slow. Another problem is that the dating may be ambiguous because the directional secular variation rarely departs more than ca. 20°

from the axial dipole field direction, while the variation of archaeointensity is generally of the order of plus or minus 50% of the present-day value. This means that the geomagnetic field recovers a very similar direction and/or intensity after a certain time. This is the case in Germany for late medieval and Roman times, or for Iberia around 550 and 1600 CE (Gómez-Paccard et al. 2006). Here, prior archaeological information must help to restrict the possible dating interval. Archaeomagnetic dating in regions or time intervals not yet covered with archaeomagnetic data is possible by using calibration curves obtained from global modeling of the secular variation (e.g., Pavón-Carrasco et al. 2011, and references therein). But such results have to be used with caution because the calibration curves are much less well constrained, may be biased, and because of the ambiguity mentioned above.

The most commonly used scientific dating method may be radiocarbon dating, which becomes very imprecise because of calibration curve plateaus caused by variation in the radiocarbon production rate. Archaeomagnetic dating may have the potential to overcome this particular problem because it seems to be most precise in such periods. During the Early Medieval and Hallstatt radiocarbon plateaus, the archaeomagnetic field shows, at least in Europe, a relatively strong movement of direction accompanied by strong and rapid variations in archaeointensity (Genevey et al. 2016; Hervé, Chauvin, and Lanos 2013).

Calibration curves

Development of a calibration curve requires data from a region with a typical radius of 500–1,000 km, and from several centuries or millennia, covering each century with a minimum of two data points. For curve calculation, the state of the art is represented by sliding window or Bayesian (see BAYESIAN STATISTICS) statistical techniques which provide continuous curves of declination, inclination and/or intensity, and take into account prior knowledge such as error of age and magnetic parameters or stratigraphy (e.g., Lanos et al. 2005).

Global calibration curve models use the various databases built for archaeomagnetism (e.g., Arneitz et al. 2017). The Bayesian curve building itself is also able to provide *a posteriori* dating for each feature involved (Lanos 2004).

Universidad Complutense de Madrid, Spain

Introduction

Archaeomagnetism, the study and interpretation of the magnetic properties of archaeological baked materials, is an interdisciplinary topic that requires expertise both in geophysics and in archaeology. From the study of the *thermoremanent magnetization* acquired by well-dated archaeological features, geophysicists have established master curves of the variation of the geomagnetic field for a particular region. Once established, these curves can be used as a dating tool for undated baked archaeological materials. *Archaeomagnetic dating* is probably the best known application of paleomagnetism to archaeology, but the study of the magnetic properties of archaeological materials also provides a wealth of information, including insight into their composition, provenance, and paleofiring conditions. Successful archaeomagnetic research thus depends on input from these two domains and, in turn, archaeomagnetism is capable of providing useful information to both disciplines. This technique is based on the capacity of certain archaeological materials that are rich in iron oxides, heated to several hundred degrees Celsius, to retain a stable *thermoremanent magnetization*. This magnetization is locked in the archaeological material until further heating, and preserves information on the direction and intensity of the past geomagnetic field at the place and time of the last heating-cooling cycle. If the date of the last firing of the archaeological feature is known and the thermoremanent magnetization remains unaltered throughout the time period between its acquisition (the last heating of the feature)

and the moment of measuring the archaeological sample, it can be used to make an indirect observation of the past geomagnetic field vector for a particular location and specific time.

Physical background

The basic phenomenon that makes archaeomagnetism possible is the ability of certain archaeological clay-rich materials heated to high temperatures to preserve information about the ambient magnetic field present at time of their last cooling, which is usually the Earth's magnetic field. If materials that are rich in iron oxides (e.g., magnetite, Fe_3O_4 , and maghaemite, $\gamma\text{-Fe}_2\text{O}_3$) are heated above a certain temperature (the so-called *Curie temperature*, which is characteristic for each magnetic mineral), they become easily magnetized in the direction of the ambient geomagnetic field. On subsequent cooling below the blocking temperature, this magnetization (the thermoremanent magnetization, TRM) is locked in the material until further heating and, under certain circumstances, is also proportional to the ancient magnetic field. Iron oxides are ubiquitous in most of the clay deposits that were used in the past for the construction of archaeological features (e.g., kilns, furnaces, ovens). In addition, during their heatings, these structures often exceed the Curie temperatures of magnetite (578°C) and maghaemite ($578\text{--}675^\circ\text{C}$). Even if the original clays were not rich in such iron oxides, the heating and cooling cycles may have produced them due to thermally induced mineralogical transformations. The processes by which archaeological materials become magnetized are well founded in the physical theory of thermoremanent magnetization (Néel 1955). This theory explains how grains of magnetic minerals become permanently magnetized as they cool through their magnetic blocking temperatures in the presence of an external field. Because the cooling time for typical archaeological structures is rapid (from some hours to several days), it may be assumed that the archaeological structures provide spot readings

DOI: 10.1002/9781119188230.saseas0036

in time of the geomagnetic field direction and intensity at the time of cooling. TRM acquisition theory also provides a basis for obtaining measurements of the strength or intensity of the field, known as absolute archaeointensity or paleointensity. The study of the TRM acquired by well-dated archaeological baked materials therefore provides a unique way to recover past geomagnetic field variations in the historical past.

Historical overview

Archaeomagnetism has a hybrid origin. It evolved both from the study of the Earth's magnetism and from the study of the magnetic properties of synthetic and natural materials. The study of the origin and behavior of the geomagnetic field is one of the earliest domains of Earth Sciences, with observations made in classical times, and also is the subject of probably the first scientific treatise. In 1269 Petrus Peregrinus wrote his "Epistola", an experimental treatise on the magnetic properties of a spherical lodestone, and was the first to describe the existence of two magnetic poles in magnets. Three centuries later, William Gilbert applied this concept to the Earth, and proposed that the Earth itself acts like a great magnet (*De Magnete*, 1600). Although Gilbert's model explained a considerable part of the static field, after the discovery of the temporal variation of the magnetic declination made by Gellibrand in 1635, a whole new dimension opened up. Since then, different models have been proposed to explain the temporal and spatial variation of the geomagnetic field (see Jonkers 2003 for a review of theories of the field up to 1800). Nowadays, we know that the geomagnetic field is a dynamic phenomenon that varies on a vast range of temporal and spatial scales. The main source of the geomagnetic field is to be found in a dynamo operating in the Earth's electrically conducting iron-rich fluid outer core, about 2900 km below the Earth's surface. This portion of the geomagnetic field is often referred to as the main field. The main field varies slowly with time and space: these changes are called the secular variation of the geomagnetic field. For this reason, in order to get a satisfactory picture, the geomagnetic field must be measured at many places all around the

world. For recent times, this is done by approximately 200 operating magnetic observatories worldwide, and by satellite missions, such as the European Space Agency's magnetic field mission *Swarm* launched in November 2013, which allows observation of the field at unprecedentedly high resolution. Since the sixteenth century, when the expanding number of marine expeditions led to a great increase in the use of the magnetic compass, direct observations of the direction of the geomagnetic field have been available. However, instrumental measurements of the geomagnetic field strength were not routinely available until 1832, when Gauss discovered a method to measure absolute geomagnetic field intensities. Information about geomagnetic field variations prior to direct measurements requires indirect observations of the geomagnetic field that can only be obtained from the paleomagnetic study of well-dated geological or baked archaeological materials that preserve a record of the past geomagnetic field as a remanent magnetization.

The observation that the magnetism can survive in rocks and archaeological materials at historical and geological timescales has proved to be one of the most rewarding discoveries in Earth Sciences. Pioneering work on archaeological artifacts began in the seventeenth century when Boyle (1691) demonstrated that bricks lose their magnetization when heated to high temperature and acquire a new one while cooling. The idea that archaeological materials could be used to extend the geomagnetic record over historical times was known by the last decade of the nineteenth century. Folgheraiter (1899) summarized the method and recovered the magnetic inclination recorded by different archaeological objects. Since the times of Brunhes (1906) it has been known that the TRM acquired by baked clays is parallel to the direction of the geomagnetic field during cooling, and that the TRM remains unaltered even if the Earth's magnetic field changes. Chevallier (1925) applied the same ideas to recover directional geomagnetic field changes from historical lavas from Mount Etna (Italy). The idea of recovering the intensity as well as the direction of the geomagnetic field dates back to Folgheraiter (1899) who proposed that the ratio between the natural remanent magnetization produced by cooling in the ancient field and the TRM after cooling in the present field should be the same as the

ratio of the two fields themselves. About 40 years later, Émile and Odette Thellier produced the first reliable determinations of paleointensity from the study of archaeological materials. They developed a laboratory protocol to determine directions and intensities and indicated a series of conditions (the Thellier laws) that must be fulfilled to reliably determine the intensity of the ancient geomagnetic field. Their work culminated in the physical bases of TRM blocking and recognized the essential role of grain size and shape in the TRM acquisition process. In 1949 Louis Néel quantified these concepts in terms of the properties of single-domain grains (Néel 1955). These methods are still valid and used today (see ARCHAEOINTENSITY).

Procedures

In archaeomagnetism, the geomagnetic field vector is defined by three elements: the declination (D), the inclination (I), and the intensity (F). D is the angle between the geographic North and the horizontal component of the geomagnetic field, ranging from 0° to 360° (or 180°W to 180°E). I is the angle between the horizontal plane and the geomagnetic field vector: it ranges from -90° (up) to 90° (down). The intensity, F, is the vector strength, which nowadays ranges from 25 to 65 μT at the Earth's surface. The aim of archaeomagnetic research is to determine the values of these three elements from the magnetic study of archaeological baked materials.

For this purpose, when an archaeological feature is excavated, several oriented samples should be recovered and the TRM measured in a paleomagnetic laboratory. During this process, the reference direction must be preserved to determine the directional elements (i.e., D and I). That is not the case for intensity measurements, for which non-oriented samples can be considered. If one takes into account that the secular variation of the geomagnetic field direction is of the order of a few degrees within tenths of years, the precision of the orientation during sampling should be less than 1–2°, if possible. In this context, the most precise sampling method is to use pouring gypsum to create a horizontal surface where a reference direction is marked by means

of a solar or magnetic compass. It should be highlighted that when the structures are strongly magnetized, the use of a magnetic compass may produce important biases. Most remanence measuring equipments require regularly shaped specimens. Therefore, hand samples are generally impregnated in water-glass or ethyl-silicate in order to consolidate the samples before cutting standard cubes or cylinders. Drilled cylinders can also be directly obtained from the archaeological structures, if the materials are well consolidated.

Once prepared, these specimens are treated at the paleomagnetic laboratories following different protocols that have been established to guarantee the precise measurement of the past geomagnetic field direction. Such techniques involve stepwise demagnetization procedures. The main objective of these demagnetization protocols is to detect possible secondary records that should be subtracted to properly determine the characteristic remanent magnetization acquired during the last heating/cooling of the archaeological structure. The mean direction is derived from Fisherian analysis of several specimens per structure, and is given together with its corresponding error (see Tauxe et al. 2014 for further details). If the date of the last firing of the archaeological feature is known, the direction (D, I) of the geomagnetic field in the past for that location and specific time can be estimated. In contrast to the directional studies, which are nowadays well established, the archaeointensity determination is more complex. Up to now, there have been different proposed methods to measure the archaeointensity, with the consensus that the Thellier and Thellier (1959) derived methods yield the most reliable paleointensity determinations. These methods are based on the progressive replacement of the natural remanent magnetization of the samples (acquired in the past) by an artificial TRM acquired in a known field. Different laboratory tests should be applied in order to assure the reliability of the ancient field intensity estimation (see ARCHAEOINTENSITY). This geomagnetic element has an advantage over the directional elements (i.e., declination and inclination) because it does not require oriented samples. For this reason, baked clay objects such as fired bricks, potteries, tiles, or shards, that also exhibit a TRM, can be used to derive archaeointensities.

Archaeological applications

In archaeology, dates are often derived from different methods simultaneously, ranging from conventional archaeological typological determinations over radiocarbon or luminescence dating methods. In this context, the wealth of information stored in the magnetic record can certainly make an important contribution. The compilation of archaeomagnetic data from a particular region allows the construction of time-continuous paleosecular variation (PSV) curves. These PSV curves provide an additional dating tool (see *ARCHAEOMAGNETIC DATING OF BAKED CLAY FEATURES*) that can be an important part of an integrated archaeological dating strategy (see *DATING IN ARCHAEOLOGY*). Archaeomagnetic dating (see *ARCHAEOMAGNETIC DATING OF BAKED CLAY FEATURES*) consists of the statistical comparison of the archaeomagnetic field information obtained from an undated archaeological structure with the corresponding PSV curve. Due to the spatial and temporal variability of the geomagnetic field, the PSV curves may vary significantly from one continent to another, and therefore for dating purposes the curves need to be defined for each particular region. In this sense, the archaeomagnetic dating tool can only be reliably applied in regions with well-constrained PSV curves. The precision of archaeomagnetic dating depends on several factors and varies from case to case. The most significant are: the rate of variation of the geomagnetic field, the envelope errors of the master curve, and the error in the archaeomagnetic data derived from the undated archaeological material. It is worth pointing out that the accuracy of the PSV curves depends on the temporal and measurement uncertainties of the archaeomagnetic data on which the curves are based, and on the number of structures available for each period. This indicates not only the need to obtain additional data, but also the importance of studying well-dated materials in order to better constrain the PSV reference curves.

Archaeomagnetic dating is probably the most known application of archaeomagnetism to archaeology, but the study of the magnetic properties of archaeological materials also provides a wealth of information, including insight into their composition, provenance, and paleo-firing conditions. For example, anthropogenic

cave sediments usually contain multiple burning events that can be magnetically studied to determine the temperature of the last heating undergone by the materials, to evaluate to what extent a burning event might be affected by post-depositional processes, or to identify temporal differences between different combustion events (see Carrancho, Herrejón-Lagunilla, and Vergès 2016 for further details).

State-of-the-art and future challenges

Since the pioneering archaeomagnetic studies performed in the second half of the twentieth century, the techniques of archaeomagnetism have been extended and developed. The production of new archaeomagnetic data has strongly increased during the last years (see Brown et al. 2015 for a recent compilation). As a direct result, different regional PSV curves for the three geomagnetic field elements (D, I, and F) are now available, particularly in Europe, the Middle East, Japan, Korea, central and southwestern North America. Different statistical techniques such as moving-average running windows, Bayesian statistics, bootstrap algorithms, or the Markov chain Monte Carlo method are applied to obtain these PSV curves. These curves are currently used for dating purposes. Recent archaeointensity studies show that the geomagnetic field has exhibited numerous short-lived, regional maxima in intensity at various times and locations. These phenomena, not captured by current global geomagnetic field models due to their limited temporal resolution, are still poorly understood. More archaeointensity data are essential to gain insight into the spatial and temporal evolution of these intriguing phenomena. At global scales, archaeomagnetic data have been used to generate continuous spherical harmonic geomagnetic field models, which allow reconstruction of past changes in the geomagnetic field not only at the Earth's surface, but also at the core-mantle boundary. For this reason these models are of invaluable interest for scrutinizing core dynamics over centennial and millennial timescales. The robustness of geomagnetic field models is limited by uncertainties arising from geographical and temporal sampling biases in current databases. In particular, the crucial importance of improving

data coverage for the Southern Hemisphere has been recognized, since the number of data for this region is still too low to infer a reliable estimation of past geomagnetic field changes. Another important issue that should be resolved in the near future is to establish a set of criteria that guarantee the reliability of archaeomagnetic data before using them for modeling purposes. It is safe to say that the more replicate specimens that are measured, and the more samples from different recording media that are measured yielding consistent results, the more confidence we can have in the final result. Recent results confirm the crucial relevance of TRM anisotropy corrections when studying past geomagnetic field strength of highly anisotropic objects such as pottery or bricks. Biases of more than 50% in archaeointensity estimations are often observed if this correction is not properly applied. Future studies must focus on the acquisition of new high-quality data from unexplored regions.

Argon–Argon Dating

SÉBASTIEN NOMADE

LSCE-CEA, Université de Versailles Saint-Quentin et
Paris-Saclay, France

Introduction

The argon–argon dating method (Ar–Ar hereafter) is based on the same radioisotopic decay system as ^{40}K – ^{40}Ar dating (K–Ar hereafter). It is based on the natural, spontaneous radioactive decay of an isotope of potassium, ^{40}K , at a known rate, to produce an isotope of argon, ^{40}Ar . The Ar–Ar method was established by Merrihue and Turner (1966), and led to improvements that eliminate problems intrinsic to the K–Ar method. The terrestrial abundance of the parent isotope, ^{40}K , and the slow rate of its decay (1.25×10^9 years), combined with numerous technical and procedural improvements, especially the single-crystal total-fusion approach developed more than 25 years ago, have made this method one of the most versatile, precise and accurate of all radioisotopic dating tools applied to volcanic materials. Ar–Ar age uncertainties are usually given at the $\pm 95\%$ confidence level or otherwise specified. It is now usual to find Quaternary ages with absolute precision and accuracy $< 0.5\%$.

Basis

^{40}K undergoes branched decay by two modes (Steiger and Jäger 1977) into ^{40}Ca ($\lambda_\beta = 4.962 \pm 0.009 \times 10^{-10}$ y) and to ^{40}Ar ($\lambda_\epsilon = 5.808 \pm 0.004 \times 10^{-11}$ y). The decay of ^{40}K into ^{40}Ar is expressed by a total decay constant, λ , that is the sum of decay constants, $\lambda_\beta + \lambda_\epsilon$ ($\lambda = 5.543 \pm 0.010 \times 10^{-10}$ y). The proportions of K isotopes at any time in Earth history are uniform, with the following percentages: $^{41}\text{K} = 6.7302\%$; $^{40}\text{K} = 0.01167\%$; $^{39}\text{K} = 93.2581\%$. Argon is variable over time in isotopic composition because of its radiogenic

production ($^{40}\text{Ar}^*$) from ^{40}K as described in Equation (1). The atmosphere (“air” hereafter) contains isotopically homogeneous Ar, with abundances of ^{36}Ar , ^{38}Ar , and ^{40}Ar with percentages of $0.3336\% \pm 0.0004$, $0.0629\% \pm 0.0001$ and $99.6035\% \pm 0.0004$ respectively (Lee et al. 2006). From Equation (1), it is possible to derive the basic age Equation (2).

$$^{40}\text{Ar}^* = \lambda / \lambda_\epsilon \, ^{40}\text{K} (e^{-\lambda t} - 1) \quad (1)$$

$$t = 1/\lambda \ln [^{40}\text{Ar}^*/^{40}\text{K} (\lambda/\lambda_\epsilon) + 1] \quad (2)$$

The $^{40}\text{Ar}^*$ produced after a volcanic eruption (daughter), as well as the quantity of ^{40}K remaining (parent), must be determined in order to calculate a sample age (see Equation (2)). To determine the concentration of $^{40}\text{Ar}^*$ in a sample, a noble-gas mass spectrometer is used. First, the total abundance of ^{40}Ar ($^{40}\text{Ar}_t$) in the sample should be measured and then corrected for the portion that is non-radiogenic, i.e. the initial ^{40}Ar ($^{40}\text{Ar}_i$) present in the sample as shown in Equation (3):

$$^{40}\text{Ar}^* = ^{40}\text{Ar}_t - ^{40}\text{Ar}_i \quad (3)$$

Correction for $^{40}\text{Ar}_i$ is made by assuming that all of this argon is associated with ^{36}Ar (also measured by mass spectrometry) in the proportion $^{40}\text{Ar}/^{36}\text{Ar} = 298.56$ (atmospheric ratio). Therefore, to calculate $^{40}\text{Ar}^*$ one simply subtracts 298.56 times the ^{36}Ar from the $^{40}\text{Ar}_t$. The quantity of ^{40}Ar left from this calculation is known as the “percent radiogenic”. It is documented that some rocks contain “excess” argon, with $^{40}\text{Ar}/^{36}\text{Ar} \ll 298.56$, resulting in spuriously older ages. The Ar–Ar method allows one to test whether the $^{40}\text{Ar}_i$ is atmospheric using isochron approaches. However, the air correction is likely to be valid with rocks that have been in contact with the atmosphere, such as eruptive volcanic materials. The determination of the parent (^{40}K) is not direct and requires neutron activation of ^{39}K to ^{39}Ar by a process known as electron capture. ^{39}Ar can be measured by mass spectrometry along with the other isotopes of argon (^{40}Ar ,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0042

^{38}Ar , ^{37}Ar , and ^{36}Ar). This allows a more precise measurement of both the parent and daughter products at the same time, using typically less than 1 mg of material. The reaction requires fast neutrons ($<1.4\text{ MeV}$ electrons) and the use of a nuclear reactor to irradiate the sample. The neutron-induced ^{39}Ar ($^{39}\text{Ar}_K$ hereafter) is directly proportional to the concentration of ^{39}K in the sample and thus indirectly proportional to the desired ^{40}K because of the consistency of the isotopic composition of K. In order to quantify the neutron fluence parameter, J , during irradiation it is necessary to measure the Ar isotopic composition, i.e., $^{40}\text{Ar}^*/^{39}\text{Ar}_K$ of a standard of known age that received the same neutron dose as the sample, that is, Equation (4). The two most widely used inter-laboratory standards for Plio-Pleistocene samples are Alder Creek sanidine (ACs-2) and Fish Canyon sanidine (FCs) with ages of about 1.1848 and 28.201 Ma respectively (Niespolo et al. 2017). The J value calculated for every sample is integrated to Equation (2) to solve the age of a sample, as illustrated in Equation (5). The $^{40}\text{Ar}^*/^{39}\text{Ar}_K$ ratio is measured in the sample by mass spectrometry.

$$J = (e^{-\lambda t} - 1) / ^{40}\text{Ar}^* / ^{39}\text{Ar}_K \quad (4)$$

$$t = 1/\lambda \ln [J ^{40}\text{Ar}^* / ^{39}\text{Ar}_K + 1] \quad (5)$$

Precision and limits

The Ar–Ar age precision and accuracy are directly related to the standard used. As a result, establishing the “true” age of standards is a very active research field. The neutron irradiation of geological material produces, in addition to ^{39}Ar , various Ar isotopes from K and Ca isotopes. These are known as “nucleogenic interferences”. These interfering Ar isotopes are measured in the sample and corrections applied using simple and pure synthetic material, such as CaF_2 and KFeSiO_2 glass, irradiated in the same reactor. These corrections are very important for young samples and/or samples with high Ca (the main source of error), explaining why low-K and/or high-Ca-bearing rocks are more difficult to date with the Ar–Ar method. Other λ values are used in the current literature, and the ages of ACs and

FCs standards given above may also slightly vary in the literature but only within 1%. Nevertheless, it is easy to recalculate the age of a sample based on a given standard age and decay constant. The $^{39}\text{Ar}_K$ formed in the reactor can recoil and can cause redistribution and/or loss of $^{39}\text{Ar}_K$ in the sample, leading to spurious older ages. The distance of recoil and quantity of $^{39}\text{Ar}_K$ lost is usually very small ($\ll 1\%$), but may be an issue in very small ($<50\text{ }\mu\text{m}$) or high volume-to-surface ratio samples. This problem explains why clay minerals and glass shards are not well suited for the Ar/Ar method.

Technical developments

Technical developments in mass spectrometry and detectors over the last 25 years now enable the calculation of an age using only Ar isotopes extracted from extremely small Pliocene and Pleistocene samples, down to individual single crystals ($<500\text{ }\mu\text{m}$ in size). This capacity has been used since the early 1990s by total fusion of single crystals, and was used initially to tackle archaeological questions. The advantage of this approach is that pyroclastic material can be dated without having been biased by xenocryst contamination. Minerals such as sanidine, leucite, biotite and hornblende are the most commonly used minerals in the Ar–Ar single-crystal approach. It is usual to depict single-crystal dating results by a mean of an age-probability diagram (Deino and Potts 1992). Such a plot is convenient for highlighting populations of crystals sharing the same age. Generally, it is accepted that the youngest crystal population corresponds to juvenile ones, and the other modes to xenocrysts. The weighted mean age of all crystals from the youngest mode is used to calculate the age of the eruption. The most recent mass spectrometers equipped with highly sensitive ion-beam multicollectors allow the dating of Lower Pleistocene single crystals of K-feldspar (sanidine, leucite) of $250\text{--}300\text{ }\mu\text{m}$ and less than 100 ka in only ten minutes. The Ar–Ar method overlapping with ^{14}C dating in the 15–40 ka range permits the intercalibration of these methods (Giaccio et al. 2017). Compared with the U–Th method, the Ar–Ar method is less versatile with respect to materials, but applicable,

unlike U–Th, to most of the Quaternary. Compared with other methods used in archaeology, such as electron-spin resonance, thermoluminescence or cosmogenic dating, the Ar–Ar method is currently more reliable and precise because most of the method's underlying assumptions are testable. In short, today, the only real limiting factor is the presence of volcanic material in an archaeological site.

Applications

Since Ar–Ar dating can only be used to date volcanic material, it is widely applied from the Plio-Pleistocene period in areas where volcanic activity is coeval with archaeological remains, such as Eastern Asia, Africa, and southeastern Europe. In archeological settings, two general cases can be found: (1) The archeological remains/traces are found embedded in a primary volcanic deposit, such as tuff, ignimbrite or lahar. In that simple case, which is rather rare, the age of the archaeological remains will be given by the age of the volcanic deposit. An example of such a case is the hominid footprints found in Laetoli (Tanzania; Deino 2011) dated at 3.66 ± 0.02 Ma, the direct age of the tuff where the footprints were found. (2) In many instances, the archeological level(s) are found sandwiched between volcanic deposits (i.e., tephra layers), which, if properly dated by Ar–Ar, will provide a bracketing age of the deposition of the sedimentary layer(s) containing the archaeological remains. A example is the remains of *Ardipithecus ramidus* (Middle Awash, Ethiopia) found in a sedimentary layer between the Gaala basal tuff and the Daam Aatu Tuff, dated by Ar–Ar at 4.419 ± 0.068 Ma and 4.416 ± 0.031 Ma respectively (WoldeGabriel et al. 2009). The very low quantity of material now needed for Ar–Ar dating also allows the use of this method as a forensic tool to identify the origin of raw material, such as obsidian (Vogel et al. 2006). Overall, Ar–Ar dating has greatly improved in precision and accuracy over the last 10 years, making it possible to work with smaller and/or younger minerals. As a result, more distal volcanic materials that could be found in archaeological sequences are now accessible to direct dating.

However, there is still a size limitation that could be overcome if the volcanic deposit could be chemically identified and therefore tied to a known eruption dated by Ar–Ar.

Climate Change and Dating

DANIEL VERES

Romanian Academy, Institute of Speleology, Romania;
Babeş-Bolyai University, Romania

ALIDA TIMAR-GABOR

Babeş-Bolyai University, Romania

Recent weather events including catastrophic hurricanes, flooding, and unusually warm or cold air spells have raised significant popular awareness of the notion of climate change. The main unknowns resolve around whether we are living in a changing climate with higher risks of extreme weather than usual, or whether the climate has changed to the extent that its long-term variability is perceptible to the human observer (IPCC 2013).

Climate in a narrow sense represents the average daily or seasonal weather, but it also involves the statistical description in terms of the mean and variability of a range of near-surface physical variables, including the amount and distribution of solar irradiation, air temperature, rainfall, and wind stress. Shifts in the mode of operation of such variables over different periods of time resulting from heat exchange between land and oceans are regionally defined as weather patterns. The most significant manifestations of weather patterns that we observe today include the seasonal recurrence of monsoons in Asia, the tropical storm belts, the El Niño Southern Oscillation that affects mainly the Americas, the North Atlantic Oscillation, and the Gulf Stream, the latter responsible for the mild winter temperatures over Europe.

As the biosphere, hydrosphere, and atmosphere are all closely interconnected in defining local, regional, and global climate trends, any disturbance affecting one or more major variables may bring about rapid, sometimes even abrupt environmental shifts. This complexity in

its manifestation defines climate change as a shift in the state of the global system that persists for an extended period of time, typically decades or longer. On longer timescales, the earth system's continuously dynamic evolution is driven by some major climate-defining players including astronomical modulation of solar irradiation, ocean heat balance and salinity changes, greenhouse gas forcing, and orographic and ice-volume fluctuations.

Various proxy data, nowadays extensively coupled with modeling experiments, are being employed in testing and simulating new hypotheses about climate variability. For example, it has been suggested that climate variability continuously shaped the distribution, composition, and vulnerability of various components of the global ecosystem (see PALEOENVIRONMENTAL RECONSTRUCTION), including humans and their material cultures they established globally. However, an issue that still compels considerable research effort is the timing of past climate events in paleoclimate records worldwide. Exploring the relationship between various modes of operation active within the climate system at any given time and location is persuasive, but the resolution and sensitivity of dating methods (see OPTICALLY STIMULATED LUMINESCENCE and DATING AND OPTICALLY STIMULATED LUMINESCENCE) applicable to any particular paleoclimate record play an equally critical role.

Looking at the past: the nature of climate change during the Quaternary

Several hypotheses have been put forward in explaining the emerging evidence of past climate variability. The major variables involved are astronomical modulation of solar insolation that drives major and long-lasting climate variability, such as the glacial–interglacial cycles, a specific feature of Quaternary climate change, to decadal and seasonal fluctuations in solar irradiance, rainfall, temperature, and runoff that are more easily perceptible to the human

observer as contemporaneous weather patterns. Quaternary climate change, its causes and regional imprint, has been the focus of substantial research since Milankovitch formulated the astronomical theory of climate. Collectively termed astronomical parameters, the eccentricity, the obliquity, and the precession of equinoxes denote variables in the earth's orbit and inclination of its axis that modulate the amount and spatial distribution of energy received from the sun. Their cumulate long-term effect is seen in the reconstructed periodicity of change, with a combination of 100-ka, 41-ka, and 23-ka cycles accounted for in paleoclimate records covering the last million years. However, orbital parameters are only one driver of major climate changes, with biogeochemical processes operating at the earth's surface and linked to gas (particularly CO_2 and CH_4), with atmospheric forcing likely playing an equally important role (Paillard 2010).

In this respect, marine sediment and ice core research has proven fundamental in our understanding of the pacing and nature of past climate change and paleoclimate sensitivity. Extensive research on marine records greatly increased the understanding of the effects of glaciation on global climates, indicating, for example, that climate changes during the transition towards the present interglacial were unexpectedly abrupt. Prior to this, most paleoenvironmental reconstructions focused on Holocene records, whose quasi-stable interglacial climate did not offer true analogs for the rapid climate variations and ecosystem dynamics that characterized glacial times. Very detailed reconstructions of past local and global mean temperatures and moisture source variations are now available for the last 800 ka from ice cores (Lang and Wolf 2011). High seasonal accumulation of snow, such as in Greenland, even allowed for seasonal time resolution for most proxy records, which provided unprecedented views on the rate of magnitude of change undergone by the global climate system during, for example, the Last Glacial Cycle.

Millennial-scale climate variability as seen in paleoclimate records

Dansgaard–Oeschger (DO) cycles

The typical feature of DO cycles is the rapid temperature increase from glacial levels to maximum warmth attained within a few decades, followed by a gradual cooling trend, terminated with a distinct cold phase lasting for centuries (Lang and Wolff 2011). Even though all DO events exhibit such variability, they vary significantly in terms of duration—from millennia to several centuries. They also appear to be grouped into larger cycles, the so-called Bond cycles, which comprise several DO events and culminated with the deposition of Heinrich layers as ice-rafted detritus in the Atlantic.

The paleoclimatic signal reconstructed from Greenland ice was extreme, with rapid air temperature shifts between stadials and interstadials of 5–16 °C, if not larger. These findings contrast with the early views of gradually decreasing insolation and slowly increasing global ice volumes throughout the Last Glacial Cycle. Unequivocally, such abrupt shifts between cold and warm conditions resulted in repeatedly unbalanced thresholds, forcing adaptation strategies for the broader ecosystem, including the Paleolithic human species.

Observational data and modeled scenarios suggest that DO cycles were triggered by shifts in the thermohaline circulation and the amount of heat delivered to the North Atlantic region by the combined ocean–atmosphere system (Ganopolski and Rahmstorf 2001). The reconstructed pattern of change suggests that a slowdown or complete cessation of deep-water formation and reduced poleward heat transfer are linked with stadial conditions; conversely, an enhanced thermohaline circulation similar to today was active during interstadials. Concurrent variations in the concentration of greenhouse gases and dust, as reconstructed from ice cores, suggest that all components of the climate system participated at least in the propagation of DO events, rendering it rather difficult to assert the triggering mechanisms.

Even more interestingly, the reconstructed interhemispheric pattern of change has a bimodal relationship directly related to changes in the

Atlantic Meridional Overturning Circulation (AMOC) modes, with the polar regions showing opposed paleoclimate signals (Broecker 1998) reflecting the so-called bipolar seesaw mechanism. Whereas Greenland was experiencing warming, the Antarctic region cooled, and vice versa, depending on the regional strength and states of AMOC. Taking a simplistic view, low to medium latitudes in both hemispheres have undergone a range of changes related to the regional imprint of the dominant north or south climate variability, and which, if further modulated by local or regional-scale particularities, such as over the continental interiors, complicate the emerging picture of past climate variability. For example, a range of intermediate signals will be recorded in proxies from the subtropical/temperate region, depending on the strengths and weaknesses of the North Atlantic versus Antarctic influences and related shifts in air circulation and moisture.

Irrespective of the triggering mechanisms, it is apparent that these changes were associated with a latitudinal migration of atmospheric circulation patterns. This resulted in increased zonality and large-scale meteorological shifts in air circulation and rainfall, primarily in the circum North Atlantic region, but also as far as eastern Asia, the Indian Ocean, South America, and the Pacific Ocean. Records from such regions show a very similar pattern of change as that observed in the Greenland ice cores, suggesting that the low-latitude monsoon system may have played an important role in the global teleconnection of millennial-scale climate variations. As such, the DO events as dated and described from the Greenland ice records form a chronostratigraphic template against which paleoclimate and chronological data arising from various other paleoclimate archives are usually tested.

Heinrich layers and Heinrich events

Early studies of marine cores recovered from the seabed of the North Atlantic Ocean led to the identification of peculiar sediment layers, far too coarse for having been transported to the open ocean solely by marine currents (Heinrich 1988). As soon as their nature was understood, the debris layers in the North Atlantic marine

records were linked to ocean-wide disintegration of large amounts of icebergs originating from the neighboring continental ice sheets. A combination of climate–ocean–ice-sheet interactions appears responsible for such periodic surges of icebergs in the North Atlantic, although it is unclear whether they simply reflect mechanics of glacier ice dynamics or climate forcing. Hypotheses have been proposed for explaining their origin, including the destabilization of ice margins by ice-load-induced earthquakes and sea-level fluctuations, the abrupt collapse of the AMOC coupled to subsurface ocean heat transfer into the North Atlantic, abrasion of the ice sheets margins by sea tides, or even catastrophic collapses of ice shelves, similar to what has been observed in recent years in Antarctica (Veres 2007).

The depositional pattern of ice-rafted detritus differs greatly among individual Heinrich layers. For most layers, the rock detritus has been linked through mineralogical screening to the Canadian Shield—evidence that links the majority of icebergs surging to the Laurentide ice sheet via Hudson Bay, where the debris layers attain their maximum thickness (Hemming 2004). Some of the Heinrich layers are characterized by complex depositional patterns, with precursory contributions of ice-rafted detritus typical of Scandinavian–British rock sources. It has been suggested that melt-water and iceberg releases from European precursory events were responsible for an initial reduction of the thermohaline circulation in the North Atlantic, which could have in turn initiated the main collapse of the Laurentide ice sheet. There is also evidence that Heinrich layers were deposited asynchronously in the Nordic Seas, which would suggest significant differences in ice dynamics or in the nature of sediment delivery by ice surging from ice sheets bordering the North Atlantic.

Biostratigraphical, chronological, and isotope modeling data suggest that Heinrich layers—as depositional horizons—accumulated very rapidly (over 500 ± 250 years; Hemming 2004). Heinrich events, on the other hand, encompass a broader time span—a notion that reflects their paleoclimate significance due to their long-lasting influence on sea surface temperature, hydrology, and atmospheric circulation. Data indicate that most Heinrich events strongly affected marine

and terrestrial ecosystems for a much longer duration than the time covered by the actual deposition time of Heinrich layers. In the isotope records from Greenland and Antarctic ice cores, Heinrich events are not distinguishable from other stadials, but as they occurred during the coldest phases of stadials, it may be that the already cold conditions exacerbated the cold climatic signal, with far-reaching consequences. Indeed, the environmental impact caused by the presence of icebergs and melt-water in the Atlantic Ocean is well expressed in marine and terrestrial paleoclimate records. Linked to a complete cessation of the thermohaline circulation, forcing a southward migration of the polar front down to ca 45°N latitude, these phenomena triggered drastic changes in moisture and atmospheric circulation patterns over most of the northern hemisphere, if not globally, albeit with a contrasting pattern of change (Hemming 2004). For example, Heinrich events have been linked to significant sea surface temperature, salinity, and productivity changes in the Atlantic, severely dry and cold events in the Mediterranean region, wet and warm events in the Gulf of Mexico and South America, and even periods of enhanced marine productivity in the Antarctic Seas.

Constraining the timing of rapid climate variability

A consistent picture of environmental change that characterized the Last Glacial Cycle unfolded mainly following the investigation of ice core records. Such data not only allowed for better constraining the timing and amplitude of millennial-scale climate changes, but also highlighted difficulties in chronologically linking data from various records on common timescale(s) (Lang and Wolff 2011). Several timescales have been proposed for polar ice records, and most intensively used in correlating and inferring synchronicity for various proxy data (Bazin et al. 2013). However, even though isotopic data from different ice cores exhibit a remarkably similar pattern in shape and amplitude over various paleoclimate events, when plotted on their individual timescales they diverge significantly. Such differences could occur because

of layer-counting errors and uncertainties in variables resulting from ice-flow modeling. These issues have now been partly solved with the construction of a new timescale for both Greenland and Antarctic records (Bazin et al. 2013), but further refinements are necessary.

Intensive research on marine cores revealed clear similarities in environmental change between such records and ice core data. Few of the marine records rely on strong individual chronologies, mainly because of chronological problems related to the use of radiocarbon dating in marine settings, and dating limitations beyond its range. Most marine records are therefore based on tuning chronological or isotopic tie-points to other records. The main paradigm of such an approach is that changes occurred synchronously, an assumption, however, that can easily lead to a scenario where possibly nonsynchronous events are compared.

For terrestrial sequences such as lake sediments, independent chronologies can be established through radiocarbon and luminescence dating (see DATING AND INFRARED STIMULATED LUMINESCENCE), by using laminated sediments, and by using tephra layers for obtaining critical chronological tie-points. Constraining the relationship between global climate change and local environmental effects, however, remains the subject of ongoing studies.

Holocene climate change

Comprising the last 11.7 ka in the earth's climatic evolution, the current interglacial period, the Holocene, has largely been considered an interval of stable environmental conditions that allowed for the emplacement of current ecotones, as well as the birth and flourishing of humankind. However, following the last deglaciation, multidecadal to millennial climate variations—both warm, such as the Mid-Holocene climatic optimum, the Roman Warm Period, and the Medieval Warm Period, and the Recent Warming, as well as abrupt and short-lasting cold events (the 9.5-ka, 8.2-ka, 6.6-ka, and 3.4-ka events and the Little Ice Age)—have been well documented by proxy data. It has been suggested that most of these have been associated with significant hydrological

regime changes. Apart from some hemispherical consistent long-term climatic trends like the climatic optimum of the Mid-Holocene, or the generally cooling climate for the last 4 ka, evidence from empirical data and modeling document an extraordinary degree of spatiotemporal hydroclimate variability during most of the Holocene. Such spatiotemporal variability is normally associated with regional shifts in air mass patterns, rain belts, and moisture availability, over both land and sea (Maslin, Stickley, and Ettwein 2001). Therefore, in order to comprehend the Holocene climate variability of a given region, the emerging picture must be integrated within much broader scenarios. The advance in the study of Holocene climate has been facilitated by the wide applications of a range of dating methods (radiocarbon especially), as well as the availability of records and instrumental data that allow for high-resolution multiproxy research. Reconstructions show that when compared to the climatic manifestations of the Last Glacial Cycle, the Holocene climate changes appear moderate; these were nonetheless significant variations that at times played a crucial role in the waning and waxing of ancient groups, especially those that relied heavily on hydroclimate parameters, such as precipitation variability for agriculture-oriented societies.

This renders the Holocene a period of significant natural climatic oscillations that in turn would have been closely linked to the development, both culturally and technologically, of our society—from the momentous shift to farming and land-use changes, to the current large-scale industrialization and anthropogenically altered condition we see today—a period that has aptly been called the Anthropocene.

Cosmogenic Dating

GILLES RIXHON

University of Strasbourg, France

Cosmogenic nuclides are defined as isotopes produced by any interaction between primary or secondary cosmic rays and matter (Gosse and Klein 2014). In contrast to the products of interactions taking place in the atmosphere (i.e., atmospheric cosmogenic nuclides such as ^{14}C), those resulting from interactions between the secondary cosmic ray flux and the atomic nuclei of minerals are named terrestrial (or in situ-produced) cosmogenic nuclides (TCNs). Among the secondary cosmic ray shower, the particles involved in TCN production at the (sub-) surface of the Earth's crust mostly are neutrons and muons (see COSMIC-RAY MUON TOMOGRAPHY). Highly energetic neutrons ($>30\text{ MeV}$) and epithermal (0.5 eV to 0.1 MeV)/thermal ($<0.025\text{ eV}$) neutrons induce TCN production through spallation and neutron capture processes, respectively. Muonic interactions imply both slow negative muons and fast muons. Whereas spallation is the prevailing production pathway within the uppermost 3–4 m of the lithosphere, the muonic contribution becomes dominant at depths greater than 3–4 m. Many nuclide species are generated from these interactions, but in order to be functional for dating purposes, they must fulfil a series of criteria (Dunai 2010; Gosse and Klein 2014), thereby limiting to six the number of TCNs commonly used as geochronometers so far. These nuclides are either stable gases (^3He , ^{21}Ne) or radioactive (^{10}Be , ^{14}C , ^{26}Al , and ^{36}Cl). Whereas quartz is the main target mineral of four of these (^{10}Be , in situ ^{14}C by contrast to atmospheric ^{14}C , ^{21}Ne , ^{26}Al), ^3He is mainly produced in olivine and pyroxene, and ^{36}Cl in calcite and feldspar.

Dating methods based on concentration measurements of in situ-produced cosmogenic nuclides yield numerical “uncalibrated” ages (Gosse and Klein 2014). They have considerably evolved over the last three decades, thanks to both

major technical and theoretical advances. On the one hand, progress in isotope mass spectrometry has allowed high-precision measurement of very low TCN concentrations in rock or sediment samples. In particular, high-energy accelerator mass spectrometers (AMS; see MASS SPECTROMETRY (MS)) developed in the 1980s can achieve extremely high discrimination against molecular and atomic interferences (Dunai 2010). On the other hand, a considerable and long-lasting effort of the community has resulted in progressive improvement of the knowledge of production rates, data processing, procedures of geochemical extraction and sampling approaches (Gosse and Klein 2014).

Depending on the aim of the study and/or the studied setting, concentration measurements of terrestrial cosmogenic nuclides allow assessment either of the duration of exposure to cosmic rays, or the duration of shielding from these. In the first case, the measured concentration of nuclide(s) is proportional to the duration of continuous exposure of surficial rocks or sediments to cosmic rays. The resulting geochronological tool relying on continuous nuclide accumulation is named *surface exposure dating*. In the second case, formerly exposed rock or sediments become permanently—or temporarily—protected from cosmic rays, implying a complete—or discontinuous—cessation of TCN production. The resulting geochronological tool relying on the differential decay of cosmogenic radionuclides is named *burial dating*. Both dating approaches are presented in this entry, but it must be borne in mind that their use is underpinned by several basic assumptions and limited by some intrinsic constraints. Consequently, distinct sources of uncertainties may affect or even bias the dating results. They fall into three broad categories: methodological (i.e., determination of site-specific production rate), observational/analytical (i.e., elevation of sampling site, sample preparation), and geological/geomorphological uncertainties (i.e., limited knowledge of the exposure history of individual samples) (Dunai 2010).

Surface exposure dating

In the framework of a single exposure episode to cosmic rays, the total concentration of cosmogenic radionuclides (C_{tot}) in any geological or geomorphological surface in a *non-eroding* environment can be expressed as:

$$C_{\text{tot}}(t, x) = \sum_i \frac{P_i(x)}{\lambda} (1 - e^{-t\lambda}) + C_{\text{inh}}(x) e^{-t\lambda} \quad (1)$$

where t is the exposure time (i.e., the “age”), x is the subsurface depth, P the production rate of the radionuclide, i (subscript) the different production pathways according to the secondary particles involved in the production of the considered radionuclide (see above), λ the decay constant proper to the radionuclide, and C_{inh} the nuclide inventory already accumulated before the onset of the exposure episode of interest (the so-called inheritance, see below). The knowledge of two variables is thus fundamentally required to compute exposure ages: the amount of cosmogenic nuclides in the sampled material measured in the AMS, and the site-specific nuclide production rate. As for the second one, its determination must incorporate both the selection of suitable scaling factors and a potential shielding to cosmic rays at the sampling site (i.e., self-shielding due to the geometry of the sampling material itself, and/or shielding caused by the neighboring topography). The application time-span of surface exposure dating is highly variable and depends on the employed nuclide(s) and the environment where the method is applied. It ranges from historical times (e.g., Little Ice Age moraines; Schimmelpfennig et al. 2012) to the whole Quaternary and the Neogene under specific circumstances.

However, geological/geomorphological surfaces do not generally remain pristine over the time-span during which they are exposed to cosmic rays. A series of processes may act on these and consequently modify their cosmogenic inventory, which is essentially accumulated at the surface and within the few meters below it. Uncertainties induced by these processes, if not considered, may strongly bias the “true” exposure age of the landform (or the event that has to be dated). These processes may affect exposure ages in two contradictory ways. On the one hand,

processes involving either a loss of matter, such as erosion, weathering, surface lowering (e.g., wind deflation, illuviation), or subsequent mass shielding of the surface, such as loess, volcanic ash, or hillslope material, may substantially lessen the cosmogenic inventory in the sample. This may cause significant age underestimations. Since erosion is disregarded in Equation 1, the latter is unsuitable to compute exposure ages in eroding settings. Assuming a steady erosion rate through time, a correction factor might be used, provided that erosion—or more generally any loss of matter—can be separately evaluated (Dunai 2010). Otherwise, only *minimum exposure ages* can be provided from surface samples. On the other hand, any nuclide inventory already present in rocks or sediments before the exposure episode of interest may cause significant overestimations of real exposure durations. This process is known as inheritance (see Equation 1). In the case of sediments, pre-exposure may occur when the studied material is exhumed from bedrock and transported or temporally stored at the (sub-)surface on the hillslopes and in the drainage network (Anderson, Repka, and Dick 1996). Several approaches may help to overcome these limitations, such as the depth profile dating method, which consists of sampling sediments at regular depth intervals. Taking advantage of the neutron-dominated production (spallation) near the surface and the muon-dominated production at greater depths, it allows a simultaneous assessment of the exposure time, the post-depositional erosion rate, and the inherited component (Rixhon et al. 2014).

Over the last two decades, many fields of the geosciences have greatly benefited from the increasing use of surface exposure dating. The most common application aims to constrain the timing of deglaciation through the dating of glacial landforms, such as boulders lying atop of moraines and/or glacially polished bedrock (e.g., Schimmelpfennig et al. 2012). In addition, a wide variety of both erosional and depositional landforms have been successfully dated; they include alluvial fans, bedrock fault scarps, fluvial terraces (both bedrock strata and alluvial fills), landslide or rockfall scarp faces, lava flows, marine terraces (both wave-cut platforms and abandoned beach levels) and wind-polished bedrock. In archaeological settings, surface exposure dating has been

or can be theoretically applied to anthropogenic structures such as human-flattened rock outcrops, ancient stone buildings, or quarry walls. TCN dating of river sediments associated with lithic industries and/or paleofauna remains represents an insightful alternative (e.g., Rixhon et al. 2014).

Burial dating

Based on the differential radioactive decay of two cosmogenic radionuclides, burial dating determines “how much time the concentrations of both nuclides have decayed”. As a function of the corresponding half-lives (λ_A and λ_B), the pre-burial ratio $[R_{A/B}(0)]$ in the same sample decreases with increasing burial duration (t_b). This can be expressed as (Dunai 2010):

$$R_{AB}(t_b) = \frac{C_A(t_b)}{C_B(t_b)} = R_{AB}(0) e^{-t_b(\lambda_A - \lambda_B)} \quad (2)$$

where the concentrations $C_A(t_b)$ and $C_B(t_b)$ represent measured concentration values in the AMS and $R_{AB}(t_b)$ denotes their ratio. ^{26}Al and ^{10}Be represent the most common nuclide pairs for burial dating, although other nuclide combinations can be implemented (e.g., ^{26}Al – ^{10}Be – ^{21}Ne). While both nuclides are produced in the same mineral (i.e., quartz), the $^{26}\text{Al}/^{10}\text{Be}$ production ratio does not depend on latitude and altitude and only slightly changes with depth. As for the ^{26}Al – ^{10}Be pair, the application time-span of burial dating firstly depends on the analytical precision of ^{26}Al measurements in the AMS and on its half-life. In practice, it ranges from the Middle Pleistocene to the beginning of the Pliocene.

In contrast to surface exposure dating, burial dating of buried sediments is virtually unaffected by eroding or weathering agents at the surface, although this method has several intrinsic limitations too. Two prerequisites must be fulfilled to use Equation 2 to calculate burial ages. Firstly, the time-span during which incomplete shielding of the sediments occurs must be much shorter than the duration of subsequent burial (= fast burial). Secondly, sediments must be continuously buried by a ≥ 30 m thick overburden in order to prevent any substantial production via muons, which occurs at shallower depths (= complete and permanent burial). However, the second condition

is not fully met in many instances, implying an incomplete shielding to cosmic rays of buried sediments. In that case, Equation 2 is no longer valid because TCN production takes place after the burial event and may substantially contribute to the cosmogenic inventory (see Granger 2014). While this postburial production may therefore bias the computation of burial ages, one must verify whether the burial event has occurred at a constant depth or at time-dependent depth. Involving the collection of multiple samples in the buried sediment or rock, the isochron method overcomes the problematic postburial production and allows dating at shallower burial depths (Balco and Rovey 2008). This method relies on the fact that the ^{10}Be and ^{26}Al concentrations are different in each sample (i.e., distinct preburial histories) but that the $^{26}\text{Al}/^{10}\text{Be}$ ratio is identical.

Sediments in caves, especially in cave-deposited alluvium, represent the most common application of burial dating, for which both basic prerequisites are regularly met (Dunai 2010). Isochron burial dating has been successfully applied so far to paleosoils buried in till and fluvial terrace sediments (Balco and Rovey 2008). Burial dating applied to cave sediments or thick fluvial sequences associated with human remains and/or lithic industries (i.e., in case of buried quartz-bearing artifacts, they can be directly dated; e.g., Pappu et al. 2011) provides meaningful new insights into archaeological and paleoanthropological issues.

Dating (Burnt) Lithics

CHANTAL TRIBOLO

CNRS (National Center for Scientific Research),
France

Introduction

Lithics, in particular those found in paleolithic sites, can be dated using luminescence dating methods.

Background

In the 1950s, Daniels and colleagues in the United States and Houtermans and Stauffer in Switzerland were the first to suggest that doses recorded by minerals could be determined using the luminescence emitted by these materials, and to define the bases of the thermoluminescence (TL) dating method (Aitken 1985). The first applications of this method, performed in the 1960s at the University of Oxford, the United Kingdom, concerned potteries and fired clays only. Further developments for dating burnt lithics came in the 1970s. The first problems that had to be overcome with lithics, compared to previous ceramic dating studies, concerned their preparation: Cutting slices of a stone fragment induced a complicated irradiation process with the artificial radioactive sources used in the laboratory, while grinding powder produced triboluminescence, an undesirable nondosimetric signal. This last problem was found to be avoidable with a simple chemical treatment of the prepared powder and this technique is still used nowadays. Methodological improvements in the 1980s allowed the application of TL dating of burnt lithics to a wide series of paleolithic sites, playing a non-negligible role in our understanding of the evolution of Neanderthals and modern humans.

For instance, in the Middle East, TL dating of burnt flints helped when discussing the filiation between Neanderthals and anatomically modern humans. In western Europe, the dating of burnt flints in various caves contributed to specifying the time range for the expansion of the Neanderthal lineage, from about 250 to 30 ka, the chronology of the different techno-complexes Neanderthal man was responsible for, and his late cohabitation with modern humans between ca. 40 and 30 ka. In North and South Africa, luminescence dating of burnt lithics helped to shed light on the cultural and behavioral evolution of anatomically modern humans. In particular, in North Africa, the Aterian culture, first believed to be younger than 60 ka, was found to have been for a longer duration, starting as early as 130 ka. In southern Africa, luminescence dating of burnt lithics suggested that early symbolic expressions, represented by engraved ochre fragments and engraved ostrich eggshells accompanying the Still Bay and Howiesons Poort techno-complexes, were much older (>60 ka) than the famous art expressions of the European Upper Paleolithic, post-dating 40 ka. Finally, the dating of burnt lithics was important for discussing the arrival of modern humans in the Americas before 20 ka, challenging the “Clovis first” paradigm, after which this continent was inhabited by humans only from 12 ka.

In most cases, luminescence dating of burnt lithics was used together with other dating methods, in particular optically stimulated luminescence (OSL) (see DATING AND OPTICALLY STIMULATED LUMINESCENCE) and infrared stimulated luminescence (IRSL) (see DATING AND INFRARED STIMULATED LUMINESCENCE), applied to sedimentary quartz and feldspar grains, respectively. In fact, since the late 1990s, most luminescence dating laboratories have focused on sediment dating and only a few currently continue working with burnt lithics. Meanwhile, comparisons of the different chronologies are highly valuable, as the methods differ in many points, thus allowing cross-checking.

An important methodological development since the turn of this century concerns the surface

dating of rocks: In such a case, the target event is the last exposure of the rock surface to sunlight, for example, before it was inserted in a building. The rest of the discussion here will deal only with the dating of burnt lithics.

Physical basis of the method

As with the radiocarbon dating method, the physical phenomenon on which the luminescence dating method is based is radioactivity: Decays of radioelements occur with known, well-defined rhythms and constitute a natural clock. However, instead of measuring the remaining number of atoms, as is the case with the radiocarbon method, one exploits the radiative energy released during the decay by natural radioisotopes and absorbed by all the materials and then by the burnt lithics. Indeed, all sediments and rocks contain a small amount of uranium (^{235}U and ^{238}U series), thorium (^{232}Th series), and potassium (^{40}K) whose decay is slow enough to be considered as having been constant over the last hundreds of thousands of years. The amount of energy (or dose when the energy is based on the mass of material) absorbed by lithics thus depends primarily on the U, Th, and K contents and on the duration of the irradiation. Cosmic rays contribute to this dose. Therefore, the basic idea for luminescence and also electron spin resonance (ESR) (see DATING AND ELECTRON SPIN RESONANCE (ESR)) dating methods is to determine the total amount of dose absorbed by the sample from a starting point, on the one hand (equivalent dose in Gray (Gy)), and the rate at which the dose was absorbed (providing it was constant), on the other hand (dose rate in Gy/ka). The ratio of the equivalent dose to the dose rate gives the duration of the irradiation, and therefore the age being sought.

These methods are usually called paleodosimetric methods and they differ mainly with regard to the material studied, the zeroing event, and in the way the equivalent dose is determined. In the case of burnt lithics, the zeroing event is the last heating, for example, in an ancient hearth or under lava flows, and the luminescence properties are exploited to determine the

equivalent dose. Indeed, once a stone artifact is heated at high temperature (e.g., 500 °C), the memory of previous natural irradiations is lost. However, after subsequent irradiation (i.e., during its burial in the sediments) and under thermal (TL) or optical (OSL) stimulation, there is an emission of light whose intensity is related to the amount of radiative energy received since the last zeroing. This property is related to the discrete energy levels that charges (electrons and holes) can populate in crystals (band models) (see OPTICALLY STIMULATED LUMINESCENCE and THERMOLUMINESCENCE).

The precision of the method is about 10 percent at 1σ (68% confidence). The main limitation for the accuracy is that the assumption concerning the stability of the dose rate is not always true: Eventual changes in water content and transport of radioisotopes cannot easily be detected and taken into account.

The lithics on which luminescence dating is applied are mainly flints, cherts, quartzites, silcretes, vein quartz, and chalcedony.

Sampling

While getting a lithic in hand from an excavation and bringing it back to the laboratory does not present any particular difficulty a priori, several points related to the equivalent dose and dose rate determinations must be carefully taken into account in the field. In particular, it should be remembered that the luminescence signal must have been fully reset before burial. For flints and cherts, marks on their surface like cracks, cups, and reddening are typical of past heating. For quartzites and silcretes, the visual inspection is less informative and sampling is rather based on the location (e.g., a stone discovered in or close to a hearth). Further tests must be conducted in the laboratory in order to check that the past zeroing was sufficient to erase all the dose accumulated by the crystal before the event we seek to date. Even though most stone samples look opaque, it has been demonstrated that long exposure to sunlight can evict electrons from traps and then induce a bleaching of the luminescence signal down to 1 cm depth. It is therefore recommended

that the lithics that might be of interest for luminescence dating are protected from light once uncovered.

The dose rate is composed of two distinct parts: (1) the “internal” part, due to alpha and beta particles whose travel ranges in siliceous materials are 20 μm and 2 mm, respectively, and which originate from the sample itself (the beta and alpha dose coming from the surrounding sediment is usually neglected when the outer 2 mm of the stone is removed by sawing); (2) and the “external” part, due to cosmic rays and gamma rays. While the former can go across several meters of rocks, the latter have a travel range limited to about 30 cm. As a consequence, most of the external dose usually originates from a sphere centered on the lithics and having a 30-cm radius. However, because of the excavation, this virtual sphere is often destroyed, and therefore the gamma dose rate must be estimated from the closest stratigraphic profiles. Nevertheless, since the gamma dose rate can be spatially variable, it is recommended that the selected stones be as close as possible to a section whose radioactivity is representative of what the lithics experienced during their burial.

Preparation

Preparation of lithic artifacts includes mechanical and chemical treatments. All are done under subdued red-light which does not significantly affect the luminescence signals. First, the stone is sawed so that the outer 2 mm is discarded, as previously mentioned. The core is then crushed in order to obtain a powder that can be easily manipulated and irradiated (e.g., around 100 μm) (Figure 1). The powder is treated with hydrochloric acid to remove carbonates and avoid triboluminescence, and oxygen peroxide to remove eventual organic material. H_2SiF_6 is also sometimes useful for removing eventual feldspar grains. The powder is then rinsed, dried, and mounted on small discs or cups and loaded in the luminescence reader.

Equivalent dose

A variety of protocols can be applied in order to estimate the equivalent dose of burnt lithics, depending on the material (e.g., quartzites and silcrete versus flints and cherts), the signal (TL, isothermal TL, OSL; ESR has also been attempted), the wavelength chosen for detecting the luminescence signal, and the number of aliquots (multi-aliquots versus single aliquots).

For both flints and quartzites, the most widely used protocol exploits the TL signal and multi-aliquots (Valladas 1992). It requires the measurement of two series of TL signals detected in the blue emission band (Figure 2). For the first one, a series of known (beta or gamma) doses is given to aliquots from a natural sample and the measurement of their TL signals allows the building of an “additive” growth curve. The intercept of this curve on the x-axis gives an estimate of the equivalent dose (D). Meanwhile, the TL signal grows more slowly at low doses than at higher doses (supralinearity), so a correction must be done. The second series of measurements is made after the natural signal is erased (thanks to heat: for instance, 90 min at 350 °C) and a series of known (beta or gamma) doses are given. The extrapolation of the “regenerative growth curve” to the x-axis gives the supralinearity correction (Δ). The equivalent dose is calculated as the sum of D and Δ . Alternatively, the additive growth curve can be slid on the regenerative growth curve so

Figure 2 TL glow (a) and growth curves (b) for a quartzite sample. (a) TL glow curves for known doses added to the natural dose (black triangles) and doses added after zeroing (white diamonds); the dashed line with error bars represent D_e calculated when signals are integrated on 5 °C intervals (plateau test). (b) Additive (black diamonds) and regenerative growth curves (white squares); gray diamonds represent the additive growth curve after the slide toward the regenerative growth curve has been optimized. The dashed line with error bars represents ratios between the slide curve and regenerative curve.

that the ratio between the two growth curves is minimized (slide or normalization method): in that case, the slide length equals the equivalent dose.

A plateau test is used in order to check the validity of the equivalent dose: The equivalent dose is calculated following one of the two methods mentioned above as a function of the heating temperature. In case the geological dose (absorbed before the event to be dated) was not fully reset, the equivalent dose rises with

the temperature, whereas with a proper resetting, the equivalent dose is independent on the temperature (on most of the whole stable TL peak).

Some attempts were made to develop single-aliquot protocols, which have the advantage of requiring less material (allowing the dating of smaller samples) and permitting replication of the equivalent dose estimates. Such protocols, in particular the so-called single-aliquot and regenerative (SAR) dose protocol, are routinely used in the OSL dating of quartz grains extracted

from sediments. Some researchers studied the possibilities of exploiting the OSL signal in flints. However, they noticed that only some of them had a significant OSL signal and the method could not be generalized. Others used the orange-red TL signal in their single-aliquot approach. They suggested that the sensitivity (amount of light per unit of dose) of flints, measured in the orange-red waveband, was not changing much during the TL measurement, contrary to the most widely used blue TL signal. A short SAR protocol was proposed, but this did not seem to be efficient for most samples and cannot be used routinely.

For quartzites and silcretes, researches were also conducted to develop single-aliquot protocols, using the blue isothermal TL signal or OSL signals. In this last case, it seems that standard SAR protocols can be applied, providing that the samples were protected from light after they were uncovered. However, using the TL signal gives more direct information about the zeroing by heat (plateau test) before burial and this method remains the one that is preferred.

Dose rate

Methods for estimating the cosmic and gamma dose rate do not differ from those used for dating sediments and ceramics: Cosmic dose rate is calculated from the geographical coordinates, elevation, and burial depth. For the gamma dose rate, the measurements are done in the nearby sections, as previously mentioned. This can be performed with either a gamma field spectrometer or various types of dosimeters. They are inserted in the layers where the samples come from, at a depth of 30 cm, from a few minutes for the field gamma spectrometers, up to several months for the dosimeters.

It is also possible to reconstruct the gamma dose rate from the U, Th, and K measurements of the different constituents of the 30-cm-radius sphere around the sample. However, this might require a lot of work in complex sediments since the whole geometry must be recorded in the field, and samples representative of each constituent must be taken during the excavation and analyzed to determine their U, Th, and K contents.

Differences among lithics and ceramics and sediments are mainly due to the internal (beta and alpha) dose rate: Contrary to these last mentioned materials, the powder on which the equivalent dose is measured for lithics is not always made of well-defined grains extracted from the sample, but of aggregates of grains that were cemented (silicified) within the stone. It is thus not possible to get rid of the alpha dose rate by etching the powder with hydrofluoric acid, as is usually done with sedimentary quartz grains. The sensitivity to alpha particles (i.e., the amount of luminescence per given dose) is much lower than the sensitivity to beta, gamma, and cosmic rays. While it is not very variable in quartz grains (and so in quartzites, silcretes, etc.), it varies much more in flints and must be systematically determined for each sample.

The U, Th, and K contents in the lithics are measured on a portion of powder extracted during the sample preparation. Different methods can be used, such as high-resolution gamma spectrometry, inductively coupled plasma mass spectrometry (ICPMS), or neutron activation. Then, the distribution of the radioisotopes within the stone must be discussed. In flints and cherts, because of their cryptocrystalline structure (Figure 3a), it is usually assumed that the radioisotopes are distributed homogeneously. Therefore, all the emitted dose is absorbed by the crystals; that is, no attenuation factors are needed for calculating the dose rate. In quartzites and silcretes, the radioisotopes can, in most cases, also be assumed to be homogeneously distributed outside the quartz grains. Meanwhile, these grains are much larger than in flints (Figure 3b). For the beta dose, the typical sizes and the distances between grains imply, as in flint, that all the emitted dose is absorbed in the quartz grains, and again, no attenuation factors are needed. However, the grain size being as large as or larger than the alpha travel range, attenuation factors must be taken into account for calculating the alpha dose rate. Thin sections may be useful to determine the mean grain size within the sample.

The hypothesis of a homogeneous distribution is not always true, however. For example, some of the radioisotopes can be concentrated in some minerals (like zircons, very rich in U), present in low numbers in the lithic material, or along cracks. In that case, the emitted rays and particles

Figure 3 Thin sections of (a) a flint sample and (b) a quartzite sample. Both pictures were taken with natural light.

will not reach the luminescent crystals and the dose rate, if calculated assuming a homogeneous distribution, will be overestimated. Hence, it has already been noted that flint presenting very high U, Th, and K contents led to age underestimates.

Advantages and drawbacks of dating lithics compared to dating sediments

As mentioned earlier, most luminescence laboratories have experience in sediment dating, while only a few currently date burnt lithics. The reasons might be several. Suitable lithic artifacts are more difficult to find than quartz or feldspar grains, which are in the surrounding sediment. Because of the distance between the sample and the measurement points, the determination of the gamma dose rate requires many more measurements than for sediment dating in order to estimate the spatial variability and ensure that a representative estimate is obtained. The alpha sensitivity must be determined for each sample (which implies that the laboratory is equipped with a calibrated alpha source).

However, the dating of lithics presents several advantages over the dating of sediments. It is more directly related to human activity since the dated event is in most cases the heating in a hearth. The TL signal has a higher saturation rate than the (quartz) OSL signal, so that older samples can theoretically be dated. And last but not least, the beta and alpha dose rates are less prone to environmental changes (changes in water circulation, transport of soluble radioisotopes implying unstable dose rate, and so on) in lithics than in sediments.

Dating and Electron Spin Resonance (ESR)

MATHIEU DUVAL
Griffith University, Australia

Introduction

Since the late 1940s and the development of the radiocarbon (C-14) method, a large number of very diverse numerical dating techniques have been developed in order to address the increasing need for robust chronological data in archaeology. There is indeed no ideal method that can provide accurate age results on any kind of sample, in any sedimentary context, and for any chronology. In contrast, by definition the use of a dating method, even the most established ones like C-14, uranium-series (U-series) (see URANIUM-SERIES) and argon-argon (Ar-Ar) (see ARGON-ARGON DATING), is limited by a range of intrinsic constraints and based on some implicit assumptions. As a consequence, sometimes these methods simply cannot be used at a given archaeological locality. For these reasons, the development and use of other geochronological tools, perhaps less popular and less standardized, such as electron spin resonance (ESR, also sometimes known as electron paramagnetic resonance (EPR)), luminescence (see DATING AND INFRARED STIMULATED LUMINESCENCE; DATING AND OPTICALLY STIMULATED LUMINESCENCE; and DATING CERAMICS AND LUMINESCENCE), and terrestrial cosmogenic nuclides (TCN) dating (see COSMOGENIC DATING), is essential. The ESR phenomenon was described by E. Zavoisky in the mid-1940s and first used as a dating tool a few decades later (Ikeya 1975). Since then, the technique has been tested and developed on a wide range of materials, including phosphates, carbonates, and silicates (an overview may be found in Ikeya 1993). Although less well known than other numerical dating methods, ESR has nevertheless become a landmark in Quaternary geochronology over recent decades, and was

demonstrably found to be especially useful for Paleolithic sites beyond the radiocarbon time range (ca. 50 ka) and/or located in nonvolcanic areas.

Basic principles

ESR is a radiation exposure (or paleodosimetric) dating method based on evaluation of the effects of natural radioactivity on materials over geological times, similar to methods centered on luminescence phenomena. These effects are quantified in terms of radiation dose—that is, the amount of energy absorbed by a given material due to its exposition to radiations originating from natural radioactivity. At a microscopic level, this interaction creates unpaired electrons that are trapped in the crystal lattice of a material. They give rise to an ESR signal whose intensity is directly proportional to the number of trapped charges, and thus to the amount of radiation dose absorbed by the sample over time. The magnitude of this dose is directly dependent on the intensity of the natural radioactivity present in the sample and its surroundings, and duration of the exposition (Ikeya 1993). The basic ESR age equation may be expressed as follows:

$$D_E = \int_0^T D(t) dt \quad (1)$$

where D_E is the equivalent dose (in Gray (Gy)), which is an estimate of the paleodose—that is, the total dose absorbed by the sample during the time elapsed between the zeroing of the ESR clock ($t = 0$) and the sampling (today (T), $t = T$)—and $D(t)$ is the dose rate (usually in Gy/ka or $\mu\text{Gy/a}$), or annual dose, which is the average dose absorbed by the sample in one year. In many cases, the dose rate is constant over time, and the equation may then be simplified as follow:

$$T = \frac{D_E}{D} \quad (2)$$

where T is the ESR age of the sample—that is, the time of exposure of the sample to natural

DOI: 10.1002/9781119188230.saseas0148

radioactivity since the ESR signal has been last reset to 0.

Analytical procedure: a brief overview

To make it simple, the ESR dating analytical procedure consists of the determination of the two main parameters D_E and D . On the one hand, D_E is obtained using ESR spectroscopy, by artificially aging the samples at increasing irradiation doses in order to describe the behavior of the studied signal. A dose response curve showing the ESR intensity versus the dose is obtained, which enables determination of the dose absorbed by the material between $t = 0$ and T (today). On the other hand, the dose rate is obtained from evaluation of the amount of radioactivity within the sample and its surroundings, through a combination of in-situ and laboratory measurements using a wide range of different analytical techniques. The value is then attenuated according to different correction factors related to the material's density, geometry, and thickness, or water content. Further details about the analytical procedure may be found in Duval (2017).

Main dating applications

The first ESR dating study by Ikeya (1975) was performed on speleothems, but nowadays the most popular ESR applications in archaeological contexts are undoubtedly on optically bleached quartz grains extracted from sediment and fossil tooth enamel.

Because quartz is one of the most abundant minerals on the earth's surface, it is naturally present in many of sedimentary contexts that frequently document archaeological evidence (e.g., cave infillings and fluvio-lacustrine deposits). Similar to optically stimulated luminescence (OSL) dating, ESR dating of sedimentary quartz is based on the study of light-sensitive signals whose intensity is reset under sunlight exposure. This phenomenon is called optical bleaching and mostly occurs during sediment transport. Once the sediment is buried, and thus sheltered from sunlight, the ESR signal measured in those quartz samples increases as a result of their interaction with radiations from natural radioactivity.

Specific details about this application may be found in a review by Tissoux (2015). In particular, recent development of the multiple centre approach in the early 2000s has contributed to increasing the reliability of the ESR age results produced, by enabling better constraint of the inherent uncertainty related to the potential incomplete bleaching of the ESR signal during sediment transport.

After the first dating attempts performed in the early 1980s on fossil bones, studies were rapidly focused on fossil teeth instead, because these are usually better preserved in archaeological sites and less sensitive to diagenetic processes that could alter their structure and reset, partially or totally, their ESR signal. Tooth enamel is known to be an excellent dosimeter, that is, a material able to register a dose from a few milliGray to several thousands of Grays. However, the dose rate evaluation is made quite complex due to the fact that dental tissues are known to behave as open systems for U-series elements. In other words, unlike speleothems, for example, teeth frequently experience delayed uranium uptake after the death of the organism. As a consequence, the kinetics of the incorporation of uranium into each dental tissue should be modeled by using the U-series data collected for each dental tissue in combination with ESR dose evaluation. This is called the combined U-series/ESR dating approach. Further details regarding the ESR dating application to fossil teeth may be found in a review by Duval (2015). In particular, recent development of a semi-nondestructive procedure causing minimum damage to the teeth has opened the possibility to date highly valuable samples like hominin fossil teeth whose age lies beyond the radiocarbon time range.

An overview of recent methodological developments and a discussion about the current challenges faced in ESR dating of fossil teeth and quartz grains may be found in Rixhon et al. (2017). Additionally, many other materials have been tentatively dated in archaeological contexts, including geological apatite, corals, mollusc shells, snails, and burnt flints. A nonexhaustive overview is provided in Table 1.

Table 1 Examples of ESR dating applications in archaeological context published since the 1990s (see references in Duval 2017 and Ikeya 1993 for earlier works).

<i>Material</i>	<i>Dated sample</i>	<i>Event (re)setting the clock to 0</i>	<i>Correlation with archaeological evidence</i>
Carbonate	Cave deposits (speleothem, stalagmite, flowstone)	Crystallization (formation of mineral)	Usually provides a minimum or maximum age constraint on hominin occupation found in a layer located below or above the carbonate formation
	Terrestrial mollusc shell or snail	Crystallization (formation of mineral)	If shells have been brought by hominins, or are found in association with archaeological evidence, they may be considered as coeval with hominin occupations. Note: Life time of the organism is usually considered to be negligible in comparison with the geological time elapsed since burial of the shell
Phosphate	ESR dating of fossil teeth	Crystallization (formation of mineral)	If mammal fossil teeth have been brought by hominins, or are found in association with archaeological evidence, they may be considered coeval with hominin occupations. Note: Life time of the organism is usually considered to be negligible in comparison with the geological time elapsed since burial of the tooth
	ESR dating of authigenic terrestrial apatite veins	Crystallization (formation of mineral)	Apatite is formed from diagenetic (i.e., post-depositional) processes within sedimentary deposits, and can therefore only provide a minimum possible age for any archaeological evidence found in the same layer
Silicate	Optically bleached quartz grains extracted from sediment	Optical bleaching	ESR provides a burial age for sediments that may contain archaeological evidence, and can be then considered coeval with hominin occupations, if no reworking is observed
	Heated quartz grains extracted from sediment	Heat	If the heat may be related to fire due to anthropic activity, the material dated by ESR can then be considered coeval with hominin occupations, if no reworking is observed
	Burnt quartz pebbles and flints	Heat	If the heat may be related to fire due to anthropic activity, the material dated by ESR can then be considered coeval with hominin occupations, if no reworking is observed
	Quartz grains extracted from pottery	Heat	Directly related to anthropic activity

Main pitfalls

By definition, the use of any dating method is limited by a range of intrinsic constraints and based on some implicit assumptions. Because these are very rarely openly stated, expectations regarding numerical dating methods from nongeochronologists are sometimes unrealistic. Consequently, it is worth recalling here that ESR can only work under the following conditions:

- Unlike many radiometric methods *sensu stricto* (e.g., C-14, U-series, Ar-Ar) for which only the sample to be dated is needed to produce a numerical age result, paleodosimetric methods such as OSL, thermoluminescence (TL), and ESR require additional information about the surrounding environment to ensure a correct dose rate evaluation. In other words, a sample out of context cannot be dated. This is usually not a problem with ESR dating of quartz, as sediment samples are collected in situ, but may sometimes be more complicated with fossil teeth. As teeth can be taken from collection, the exact original (geographical and stratigraphical) location sometimes may be unknown, or the layer/outcrop/site may no longer be accessible. In this case, some precautions should be taken during the excavation by collecting the sediment surrounding the tooth. Otherwise, the absence of this information may induce later on a non-negligible uncertainty on the dose rate evaluation, and thus on the final ESR age result.
- D_E represents an estimate of the total dose of radiations absorbed by the sample over geological time. This estimate may be more or less reliable depending on whether the sample has been affected by processes leading either to a partial or complete resetting of the ESR signal (e.g., dissolution/recrystallization, heat, optical bleaching, mechanical stress), or to the increase of the main radiation-induced ESR signal by additional exposure to a radioactive source (e.g., exposure of the tooth sample to X-rays during a computed micro-tomography (μ CT) scan analysis). This may happen not

only during the geological history of the sample, but also after collecting samples, prior to or during sample preparation.

- The dose rate is evaluated by measurement of the actual radioactivity of the sample and its surroundings, and under the assumption that current conditions are representative of past history: they are considered either to have been constant over time or to have evolved following a trend that can be accurately modeled. Otherwise, if not detected, any substantial modification of the sample or its surroundings by diagenetic processes (e.g., recent uranium mobilization, water circulation, sediment reworking, bioturbation) can potentially introduce a significant bias in dose rate evaluation and, thus, on calculated age.

ESR compared with other numerical dating methods

ESR age calculation involves many parameters in order to accurately estimate the different components of the dose rate: the number may exceed 20 depending on the characteristics (size, geometry, open/closed system) of the sample considered. Each parameter has an associated uncertainty that needs to be included and propagated into the final age calculation, which usually makes a final age error (usually quoted at a 1σ confidence level) in the range of 5–15 percent. For this reason, the precision achieved with ESR may somewhat contrast with that of other reference dating methods such as Ar-Ar, C-14, and U-series, which can be < 1 percent at 2σ . However, there are nevertheless many situations in which ESR may be especially useful in an archaeological context.

The selection of a dating method at a given archaeological site depends on many parameters, such as the sedimentary context, the archaeological and paleontological material found and its preservation, and the expected chronology. Radiocarbon dating is probably the most popular and standardized method, which undoubtedly makes it the preferred option to date a wide range of materials, including fossil remains, over the last 50 ka or so. Beyond this time range, ESR dating is among the best candidates to obtain direct

ages on fossil remains (e.g., Grün et al. 2010), whereas most of the numerical methods can only provide an indirect age based on the dating of the deposits directly or indirectly associated with archaeological evidence.

U-series analyses can provide high-resolution ages on fossil remains; however, these results should be regarded only as minimum estimates, as uranium uptake in dental tissue may be significantly delayed after death of the organism. Consequently, the true age of the fossil remains would be similar or older than the U-series age. In contrast, when combined with U-series, ESR can provide a burial age for fossil teeth. Previous dating applications have shown that it can produce reliable ages from a few 20–30 ka to more than 2 Ma. Since the mid-2000s, technological developments have opened the possibility to date highly valuable samples, such as human teeth, by causing minimal damage to fossil material. One of the best examples in that regard is the recent direct dating of *Homo naledi* using a semi-nondestructive approach (Dirks et al. 2017) based on the combination of ESR analyses of enamel fragments with high-resolution U-series analyses performed by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS).

The first ESR dating application published by Ikeya (1975) showed promising results for speleothems. However, rapid development of the U-series (U-Th) dating method over the following decades has made it the best option to date carbonated formations of less than 500 ka in cave environments, as it offers faster and more accurate dating results on speleothems and other carbonated formations than ESR dating. For older deposits, the recently developed U-Pb dating method can take over as soon as the amount of uranium and lead present in the speleothems is sufficient. If not, then ESR may become an interesting alternative option, as it would make evaluation of the dose rate (and, in particular, alpha and beta dose rate components) more straightforward.

Given the wide range of materials that can be dated using ESR, the method can potentially be used in almost any Quaternary environment. This contrasts with most of the numerical dating methods, which are usually limited to a specific context. In particular, it was demonstrated to

be especially useful for Pleistocene archaeological sites beyond the radiocarbon time range and located in nonvolcanic environments (thus precluding use of the Ar-Ar method); such conditions are frequently found in Europe and northern Africa, and the number of methods that can be used in these contexts appears to be quite limited. Standard luminescence dating (mainly OSL) procedures have proven to be especially useful to date quartz and feldspar grains over the last approximately 200–300 ka in low-dose-rate environments, although it is worth mentioning that recent experimental developments have pushed the lower application limit of the method back to about 1 Ma. Because ESR signals in quartz show higher radiation saturation levels than luminescence signals, it is usually considered that ESR is better than standard OSL procedures in dating Early to Middle Pleistocene deposits (e.g., Cordier et al. 2012). Over this time range, the TCN dating method might also be applied unless conditions are not considered suitable (e.g., not enough quartz content in the sediment; limited sediment overburden).

Nowadays in Paleolithic archaeology, it has become standard procedure to combine different dating methods at a given site, in order to produce a more robust chronological framework. In other words, since the 2000s, ESR dating results have been increasingly compared with independent age control in a range of different environments. For example, both ESR on teeth and Ar-Ar dating methods provided consistent results at Guado San Nicola site (Italy) (Pereira et al. 2016). Similarly, OSL and ESR dating of quartz from fluvial deposits at the Middle Paleolithic site of Cuesta de la Bajada have produced close age estimates (Duval 2017). Other examples of successful multitechnique dating works involving direct ESR dating of hominin teeth have been documented at El Sidrón (Torres et al. 2010) and Rising Star (Dirks et al. 2017) caves. These few examples of comparative dating studies demonstrate the great potential of the ESR dating method in archaeological contexts.

To summarize, ESR appears to be a highly versatile dating method which can produce ages on fossil remains like C-14, on quartz grains like OSL and TCN methods, and on speleothems like U-series, which make it applicable in almost

any archaeological context over the last 2.6 Ma. Although the precision achieved is significantly lower than that of the more established methods, ESR is in many cases the only numerical method that can simply be used at a given site.

Dating and Infrared Stimulated Luminescence

MARTINA DEMURO and LEE J. ARNOLD
University of Adelaide, Australia

Luminescence dating of silicate minerals is based on their capacity to store energy when exposed to ionizing radiation: a process which involves charge (i.e., electrons) becoming trapped at defect sites within the crystal lattice. This trapped charge can be released upon stimulation by heat, resulting in thermoluminescence (TL), or photons, which results in optically stimulated luminescence (OSL) (see DATING AND OPTICALLY STIMULATED LUMINESCENCE and DATING CERAMICS AND LUMINESCENCE). In IRSL dating, trapped charge is released via stimulation with wavelengths in the infrared (IR) portion of the spectrum (800–1000 nm).

Quartz and feldspars are the most commonly used minerals for luminescence dating of sedimentary deposits. Although OSL may refer to any signal involving stimulation using photons, the term is generally used in the literature to refer to luminescence dating of quartz grains using blue or green light stimulation. In contrast to quartz, which is not highly sensitive to IR stimulation, feldspars can have their trapped charge readily depleted by exposure to IR photons. Hence, IRSL dating of sediments almost always refers to dating of feldspar mineral grains.

IRSL dating utilizes light-sensitive electron traps to determine the last time feldspar grains were exposed to daylight (i.e., timing of sediment deposition). The technique may also be applied to feldspar grains that have had electron traps emptied via heating, such as in pottery, but the majority of archaeological geochronology studies have tended to employ IRSL as a direct sediment dating tool. In nature, feldspar grains

that undergo sedimentary transportation prior to burial are usually exposed to sufficient sunlight to completely reset or “bleach” any previously stored charge within light-sensitive traps. Once buried and shielded from light, this charge starts to accumulate again at a rate that is proportional to the background level of alpha, beta and gamma radiation arising from within the sedimentary environment, as well as radiation from cosmic rays. IRSL dating requires an estimation of the total trapped charge accumulated since burial, expressed as an equivalent dose (D_e) in units of grays (Gy), and the rate of ionizing radiation exposure during burial, or environmental dose rate (Gy per unit time). The former is estimated via IRSL measurements made on the feldspar grains being dated, while the latter is determined from radionuclide concentrations (i.e., K, U, and Th) in the sediment and within the grains, as well as contributions from cosmic rays. The IRSL age of a sample is then calculated by dividing the D_e by the environmental dose rate.

Huntley, Godfrey-Smith, and Thewalt (1985) first reported the use of light-sensitive electron traps for determining the last time quartz grains were exposed to daylight, as part of a study employing green light stimulation. The potential for using IRSL in geological dating applications was first proposed by Hütt, Jaek, and Tchonka (1988), who measured the excitation spectra of irradiated potassium feldspar samples. These initial dating discoveries were followed in the 1990s and 2000s by the rapid development of automated instrumentation using inexpensive stimulation sources (light-emitting diodes) and single-aliquot regenerative (SAR) measurement procedures (see also DATING AND OPTICALLY STIMULATED LUMINESCENCE), as well as advanced statistical age modeling. These efforts focused on optical dating of quartz and feldspar grains extracted from sediments, and have led to standardization and proliferation of IRSL and OSL dating research in archaeological contexts.

Feldspar IRSL signal characteristics and dating procedures

One of the main advantages of using feldspars for archaeological and geological dating is their abundance in sedimentary environments. Feldspars are aluminosilicates with tetrahedral structures comprising four oxygen atoms and a silicon atom. Cations, commonly potassium (K), sodium (Na) and calcium (Ca), are inserted into the lattice where aluminum atoms replace silicate atoms. Compositions made up solely of potassium, calcium and sodium cations form end-members in ternary diagrams of natural feldspar types. Intermediate feldspars have chemical compositions containing proportions of these cations, specifically K–Na proportions (alkali feldspars) and Na–Ca proportions (plagioclase feldspars).

Investigations into the luminescence emission spectra (i.e., the wavelength of emissions) of feldspars, carried out on both sedimentary samples and on well-characterized museum specimens, have shown that their emissions are not spectrally uniform across mineral polymorphs but vary according to their elemental composition (see Krbetschek et al. 1997 for an extensive review). In general, feldspar IRSL covers several spectral bands with emissions at ~730, ~560, ~430, ~330 and ~300 nm. Ultraviolet emissions in the 290–310 nm and 320–340 nm wavebands appear in all feldspar types but are more dominant in plagioclase or sodium-rich feldspars, with the 290–310 nm emissions being less stable. Violet–blue (390–440 nm) emissions are dominant in alkali feldspars and their intensity has been positively correlated with potassium content. Yellow–green (550–570 nm) IRSL emissions dominate in plagioclase feldspars, particularly albite (sodium end-member), although this signal is not commonly used for dating. Finally, TL measurements indicate that red to far-red emissions (600–750 nm) are present in most feldspar types.

In the past, IRSL dating of feldspars has been undertaken on both fine- and coarse-grained sediment fractions. Polymineral fine-grains (4–11 μm) have been extensively targeted for dating, with special interest in IRSL applications to loess and other silt-sized sediments devoid of

coarser grains. In these studies, D_e measurements are commonly made on aliquots composed of thousands of grains that have not been subjected to heavy liquid density separation. As a result, the measured IRSL signal can arise from feldspar mixtures of unknown mineralogical composition. The routine use of coarser (>63 μm) potassium feldspar grains for dating was first described in the 1980s and has since become a commonly used approach in archaeological applications. The extraction of coarse feldspar grains from bulk sediment samples is usually performed via heavy liquid separation of the <2.58 g/cm³ fractions. Dating using coarse grains of potassium feldspar has the advantage of allowing a firmer constraint on the internal dose rate calculation, since K content can be quantified more easily (see below), and it ensures that the signal being measured comes from a purer feldspar admixture. IRSL dating studies are generally carried out on commercially available readers fitted with IR (875 nm) stimulation sources. The detection systems typically involve a blue-sensitive photomultiplier tube and blue filter packs with the aim of measuring violet–blue emissions (peak transmittance at 420 nm), as well as avoiding inputs from less stable ultraviolet signals. Single-grain IRSL dating studies have also been undertaken using readers equipped with IR (830 nm) lasers designed to stimulate individual grains with a high degree of reproducibility.

Feldspars are often considered advantageous over quartz because of several superior luminescence characteristics. Although feldspar IRSL decay and bleaching rates are slower than those associated with the main (so-called fast) OSL quartz signal (complete signal resetting may take minutes instead of seconds), their signals are usually considerably brighter than quartz. Feldspar IRSL therefore provides a preferred alternative in situations where quartz OSL sensitivity is weak or unreliable (e.g., glacially-derived sediments), as well as where quartz is absent. Additionally, feldspar IRSL signals exhibit significantly higher dose saturation properties in comparison with quartz, and can adequately record administered doses in excess of 1000 Gy. In contrast, quartz OSL typically saturates at doses of 100–250 Gy (see also DATING AND OPTICALLY STIMULATED LUMINESCENCE). These higher dose saturation

limits are advantageous for dating older archaeological sediments that lie beyond the conventional range of quartz OSL techniques.

Another potentially favorable feature of potassium feldspar dating is that a large portion of the environmental dose rate is derived from within the grains themselves owing to their high ^{40}K and ^{87}Rb contents. On average, the concentrations of these internal elements amount to $\sim 12.5\%$ and $400\text{ }\mu\text{g/g}$, respectively, which means that the internal dose rate of a potassium feldspar sample can be comparable to its external dose rate in certain samples. A relatively large internal dose rate has the benefit of minimizing the effects of poorly constrained external dose rates, which can arise from beta microdosimetry variations, undetermined variations in long-term sediment water content, or disequilibrium in the decay chain of ^{238}U and ^{232}Th . This can be particularly useful for dating archaeological contexts in which the long-term external dose rate cannot be constrained with a high degree of confidence.

Anomalous fading and feldspar IRSL

Despite the aforementioned benefits, feldspar IRSL dating has been overlooked in the past due to a form of signal instability that can result in age underestimation. Since the initial work by Wintle (1973), it has been known that luminescence signals from feldspars suffer from “anomalous fading,” making them unreliable for dating without suitable age correction. This form of signal instability is termed “anomalous” because kinetic measurements of TL peak lifetimes indicate the signal should be stable over at least tens of millions of years. However, samples that have been stored following laboratory irradiation show an unexpected decrease in their luminescence signal by as much as 50% in a matter of days to weeks; with the decrease in signal following a logarithmic time decay function. This loss of trapped charge in an otherwise stable trap is due to tunneling of electrons during burial or storage (Spooner 1994). In sedimentary feldspar grains, IRSL signal fading rates measured at low temperatures (i.e., 50°C) are usually of the order of 2–10% per decade. Observed variations in these

values have been partly linked to the crystallization history of the mineral, where poorly ordered tetrahedral structures associated with rapid cooling (e.g., volcanic feldspars) may exhibit higher fading rates than well-ordered structures.

Attempts to circumvent anomalous fading have led researchers to investigate different types of IRSL signal in feldspars, such as red IRSL and red TL emissions. Others have investigated the relationship between feldspar type and anomalous fading using both museum specimens and sedimentary feldspar grains, with the aim of determining whether certain mineral compositions are less susceptible to the fading phenomenon and could thus be targeted for dating (e.g., Spooner 1994).

However, the most common approach for dealing with anomalous fading in IRSL dating is to correct the final ages using sample-specific fading assessments. A number of methods have been proposed for this purpose. Of these, the most widely applied is that presented by Huntley and Lamothe (2001), which is based on the tunneling probability of trapped electrons. This correction method is only applicable to the linear part of the dose response curve, and so it is used primarily on samples that are less than a few tens of thousands of years old. For older archaeological samples, conventional IRSL dating (i.e., measured at 50°C) can only provide minimum age constraints.

Recent advances—overcoming anomalous fading using pIR-IR

In recent years, a significantly more stable signal from feldspars has been discovered, and is now becoming increasingly used in archaeological dating applications (see Arnold et al. 2015 for review). This signal is obtained by first stimulating the sample with IR at low temperature (i.e., 50°C) and then performing a second IR stimulation at an elevated temperature, usually higher than 200°C . The second measured IR signal is commonly referred to as post-infrared IRSL (pIR-IR), and it has been shown to be substantially less affected by anomalous fading than conventional IRSL (Thomsen et al. 2008). A large compilation of more than 150

laboratory values published to date from geologically diverse regions has revealed a global average fading rate for the pIR-IR signal of 1–1.2%/decade (Arnold et al. 2015), which is a considerable improvement from those obtained from low-temperature IRSL measurements. Additionally, some studies have reported natural pIR-IR signals that intercept the saturated portion of the dose response curve, which has been interpreted as an indication that a non-fading signal is being measured by the pIR-IR procedure.

Since the discovery that the pIR-IR signal from feldspars is less affected by (or devoid of) anomalous fading, much attention has been focused on understanding the physical basis of the phenomenon. To date, the most accepted mechanism for explaining IRSL production is the band-tail state model of Poolton et al. (2002). In this model, excited electrons may undergo tunneling or recombine following photon-assisted band-tail hopping (Jain and Ankægaard 2011). Detailed studies of signal fading, recombination processes and excitation spectra, suggest that the production of IRSL and pIR-IR arise from the same trap (Jain and Ankægaard 2011; Thomsen et al. 2008). These studies suggest that the improved stability of the pIR-IR signal is due to differences in recombination probabilities in nearby and distant electron–hole pairs, where the former have higher rates of tunneling than the latter. The process may be described as follows: trapped electrons located further from a recombination site, and which have not undergone tunneling during burial, are excited to the band-tail states by the first IR stimulation and are allowed to deplete the localized (less stable) electron–hole pairs. The depletion of these localized electron–hole pairs increases the probability for the newly excited electrons (i.e., those that are de-trapped by the subsequent high temperature IR stimulation) to recombine at distant (more stable) electron–hole pairs, resulting in a renewed IRSL signal that is substantially less affected by fading.

pIR-IR dating of potassium-rich feldspar extracts is now rapidly becoming the method of choice for archaeological samples that are too old to be dated with quartz OSL, or for samples displaying unsuitable quartz OSL characteristics

(i.e., low sensitivity). A number of pIR-IR measurement protocols have been proposed, with the majority designed to determine replicate D_e values for individual subsamples (single aliquots) of a given sample. Most pIR-IR studies have used a two-step SAR D_e measurement procedure, in which an initial low-temperature IRSL measurement performed at 50 °C is followed by a second measurement at a higher temperature (either 225 °C or 290 °C, depending on sample suitability). The use of higher stimulation temperatures may also be driven by the need to isolate a more stable signal. Further variants of this protocol include making multi-elevated-temperature (MET) measurements on the same subsample at increasing stimulation temperatures to obtain a series of D_e estimates. In this protocol, the appearance of a D_e plateau at higher stimulation temperatures is indicative of significantly reduced or absent fading (see review by Arnold et al. 2015).

Although isolating a more stable pIR-IR signal by increasing stimulation temperature may be appropriate in some samples, it has also been shown that residual doses of tens of Gy may remain even after extensive bleaching times of several hours under sunlight or artificial illumination. Moreover, these pIR-IR residuals tend to become substantially larger as the pIR-IR stimulation temperature is increased. The effect of this hard-to-bleach component may be significant in younger samples (<10 ka), for which the natural accumulated dose is relatively small. In these cases, the presence of a pIR-IR residual may result in significant age overestimation. In older samples, this residual dose may play an unimportant role and is unlikely to affect the final age beyond the existing dating uncertainties (typically ~5% at 1σ). That said, it remains important to determine the presence and size of pIR-IR residual doses on a sample-by-sample basis—by performing sunlight bleaching experiments—in order to assess whether a correction is needed when calculating the final ages. Similarly, monitoring of anomalous fading should be performed routinely in pIR-IR (or IRSL) dating studies since sample variation is commonplace (Spooner 1994), and response to measurement conditions (i.e., pIR-IR stimulation temperature) may differ considerably (Arnold et al. 2015).

Figure 1 Comparison between post-infrared IRSL (pIR-IR) ages, obtained using different equivalent dose (D_e) measurement conditions, and known sample age derived independently or via alternative luminescence methods. Results include all published studies up to 2014. The thick black line denotes a 1:1 relationship, while the thick and thin gray lines denote the linear regression for the dataset and the confidence intervals at the 95.4% confidence level, respectively. Modified from Arnold et al. (2015).

Over the past eight years, a number of pIR-IR chronologies have been produced for independently dated sediment sequences spanning ages ranging from the present day to hundreds of thousands of years ago. The latest global review, which includes all known-age studies published up until 2014, show generally good correspondence between pIR-IR ages and independent age control for samples covering Late and Middle Pleistocene timescales (Figure 1). However, a certain amount of scatter is also apparent in this known-age dataset, indicating that individual pIR-IR measurement conditions are not universally applicable to all samples. Further known-age comparison studies are needed over the 250–800 ka time period to confirm the broader suitability of pIR-IR dating over early Middle Pleistocene timescales (Arnold et al. 2015).

Current feldspar dating research is focusing on single-grain pIR-IR dating protocols, particularly in archaeological settings. This approach has the potential to provide improved pIR-IR dating reliability in complex archaeological environments that may be subjected to limited daylight exposures or the influence of

post-depositional disturbances (e.g., caves and rock shelters).

Dating and Optically Stimulated Luminescence

LEE J. ARNOLD and MARTINA DEMURO
University of Adelaide, Australia

Overview and principles of OSL dating

Optically stimulated luminescence (OSL) dating is part of a family of trapped charge geochronology techniques that utilizes the ability of natural minerals to absorb and store energy from ionizing radiation exposure over geological timescales (see also DATING CERAMICS AND LUMINESCENCE and DATING AND ELECTRON SPIN RESONANCE (ESR)). Over the last few decades OSL has emerged as one of the most widely used methods for constraining the age of Late Pleistocene sedimentary deposits preserved at archaeological sites. The increased use of OSL in archaeological dating applications has been fueled by a number of important methodological developments, including the advent of single-grain techniques. The term OSL dating is often used interchangeably with optical dating, though the latter is better thought of as a broader term encompassing various luminescence dating signals produced by visible light stimulation (OSL and thermally transferred OSL (TT-OSL)) and exposure to near-infrared radiation (infrared stimulated luminescence (IRSL) and post-infrared IRSL (pIR-IR); see also DATING AND INFRARED STIMULATED LUMINESCENCE).

OSL dating is most routinely applied to silicate minerals, particularly quartz grains, and is based on the principle of measuring light-sensitive, trapped charge populations to determine the amount of time that has elapsed since natural minerals were last exposed to daylight. These charge populations accumulate at localized metastable defect sites within the crystal lattices of buried mineral grains as a result of exposure to ionizing radiation from the surrounding sediments (naturally occurring radioactive isotopes of potassium and rubidium, and isotopes in the uranium and thorium decay series) and

from cosmic rays. A small portion of the energy delivered by the ionizing radiation is stored in the form of trapped electrons, which continue to accumulate throughout the burial period at a rate proportional to the level of natural background radioactivity. Subsequent exposure of the mineral grains to light, as typically occurs during sedimentary erosion and transportation, causes previously accumulated charge populations to be evicted from the light-sensitive traps responsible for OSL production. As a result of this process, the OSL clock is reset to zero and the emitted OSL signal can be used to measure the amount of energy stored within the mineral during burial (Figure 1a).

The repeatability of the optical resetting and signal acquisition mechanism means that OSL dating is one of the few radiometric methods that can be used to directly constrain the timing of sediment deposition events. In archaeological studies, OSL dating offers a viable means of both reconstructing site formation histories and providing indirect ages on cultural artifacts or fossils buried within sedimentary deposits. OSL is particularly well-suited for dating a diverse array of archaeological settings because it can be applied to ubiquitously occurring natural minerals and it is applicable to both silt- and sand-sized sediment fractions (typically 4–11 μm to 212–250 μm). OSL techniques also have the advantage of yielding numerical ages that do not require subsequent calibration on the calendric timescale, and they are applicable over a broad age range that extends well beyond the ~50,000 year limit of radiocarbon dating.

An implicit assumption of OSL dating is that mineral grains have been exposed to sufficient daylight prior to their most recent deposition cycle to enable complete resetting of any pre-existing trapped charge populations (Figure 1a). If this is not the case, the mineral grains being dated may retain a sizeable residual OSL signal and the calculated age is likely to overestimate the true depositional age of the sediment (Figure 1b). The rapidity with which

Figure 1 Schematic representation of the principles behind OSL dating. The graphs show how the relative size of the OSL signal changes with time following daylight exposure and burial at an archaeological site. Grains eroded from older sedimentary deposits initially have a large trapped charge population (prior OSL signal). Subsequent exposure of the grains to daylight during erosion or transportation reduces this trapped charge population (resetting event). Following burial and shielding from daylight, the trapped charge populations increase at a rate that is proportional to the level of environmental radiation until the grains are exposed to prolonged daylight and measured in the laboratory. (a) Ideal scenario in which all of the grains are exposed to prolonged daylight and the prior OSL signal is fully reset. (b) Scenario in which daylight exposure is more limited and the prior OSL signal is not completely reset. In this case, the post-burial OSL signal accumulates on top of a residual signal and the luminescence age overestimates the true depositional age of the sediment.

the main quartz OSL signal (the so-called fast component) bleaches in nature (on the order of a few seconds) means that adequate signal resetting is commonplace in aeolian environments characterized by prolonged subaerial daylight exposure. However, the potential for insufficient bleaching may need to be taken into consideration when dating certain types of archaeological sediments, particularly those accumulated by fluvial, colluvial or alluvial processes, or those deposited in caves or rock shelters.

A second important assumption of OSL dating is the absence of significant time-dependent changes in the surrounding sediment environment following burial. In particular, it is assumed that (1) the dated sediment has not been subject to major post-depositional mixing; (2) there have not been any significant time-dependent changes in sediment moisture content (or that any such temporal variations can be reasonably constrained); and (3) nuclides in the uranium and thorium decay series of the surrounding

sediment have remained immobile and/or in a state of secular equilibrium since deposition. Again, there may be instances in which these conditions are not upheld in complex archaeological settings, particularly in cave environments, and these complications must be adequately accounted for in the OSL age calculation.

OSL age calculation

To calculate an OSL age it is necessary to estimate the total radiation dose that has been deposited in a mineral grain since burial (the palaeodose) and the rate at which the accumulated radiation dose was delivered to the mineral grain in the natural environment (the dose rate). An empirical estimate of the palaeodose (known as the equivalent dose or D_e) is obtained by comparing the naturally accumulated OSL signal intensity with that obtained from a series of known doses administered using a calibrated laboratory radiation source (Figure 2a). The time elapsed since a sample was last exposed to daylight (sample burial age) may be obtained from the D_e and long-term dose rate estimate using the following equation:

$$\text{Age (ka)} = \frac{\text{Equivalent dose (Gy)}}{\text{Dose rate (Gy/ka)}} \quad (1)$$

where the amount of absorbed energy per mass of mineral is expressed in units of Grays (1 Gy = 1 J/kg).

OSL ages are given in calendric years before present (where “present” equates to the year of sample collection) and they are conventionally presented with their associated 1σ (68% likelihood) uncertainty ranges. The latter are primarily derived from random measurement and fitting uncertainties, systematic uncertainties on instrument calibration and conversion factors, and indirectly quantified uncertainties on burial history and dose rate parameters. For most archaeological samples, the combined 1σ OSL age uncertainties range between 5% and 10% depending on signal brightness, intra-sample D_e scatter, and time-dependent dose rate considerations (Aitken 1998).

The upper age limit for quartz OSL dating is dictated by the maximum number of trapped electrons that can accumulate at light-sensitive defect sites before they become completely filled or saturated, as well as the long-term stability of the trapped charge at ambient temperatures. At low dose exposures, the charge trapping rate, and hence OSL signal growth rate, is approximately linear owing to the large number of vacant electron trapping sites in the crystal lattice. Prolonged exposure to higher doses results in a tailing off of the OSL signal growth per unit radiation dose as the finite number of electron traps becomes progressively filled and it becomes increasingly unlikely for charge to be trapped at unoccupied defect sites. Eventually, when all of the available electron traps are filled, there is no additional OSL signal growth with continued radiation exposure and the upper dating limit is reached (Figure 2b). The rate of OSL signal growth with dose, characterized by the OSL dose–response curve, therefore conforms to a saturating exponential function of the form:

$$I(D) = I_{\max} \left(1 - e^{-\frac{D}{D_0}} \right) \quad (2)$$

where I is the OSL signal intensity associated with dose D , $I_{\max}$ is the maximum signal intensity at dose saturation, and D_0 describes the rate of OSL signal saturation with respect to dose and provides an indicator of the long-range dating potential of the OSL signal.

From a practical perspective, the upper limit for precise D_e determination is sometimes taken to equal roughly twice the D_0 value (~85% of the $I_{\max}$ value) on the grounds that D_e interpolation uncertainties become increasingly large as the dose–response curve approaches saturation (Figure 2b). Typical $2D_0$ values for quartz samples range between 100 Gy and 400 Gy, varying significantly on a sample-by-sample and grain-by-grain basis according to the number and type of available defect sites. Where the environmental dose rate is relatively low (e.g., 1 Gy/ka), such dose saturation limits permit reasonably precise dating back to 100–400 ka according to Equation 1. However, in higher dose rate environments (e.g., 2–3 Gy/ka), dose saturation will be reached over much shorter burial times and reasonably precise OSL dating may be restricted to within the last 100 ka. The

Figure 2 (a) Example quartz OSL decay curves for a multi-grain aliquot. The naturally accumulated OSL signal is compared with two OSL signals obtained after administering different-sized laboratory irradiations. (b) Regenerative dose response curve showing the relationship between OSL signal growth and laboratory dose. The equivalent dose (D_e) value is read off the x -axis and is determined by interpolation of the natural signal (white circle) onto the dose response curve. The characteristic saturation dose (D_0) value of the dose response curve is shown for comparison. (c) Additive dose response curve constructed by adding different laboratory doses to the natural signal (white circle). The dose response curve is extrapolated back to the x -axis intercept to calculate the D_e value. (d) Comparison of SAR dose response curves obtained using OSL, TT-OSL, pIR-IR, and supergrain OSL.

upper age range of quartz OSL therefore varies significantly depending on the D_0 and dose rate characteristics of a sample.

The lower dating limit for OSL is governed by the inherent luminescence sensitivity of the sample to low dose exposures and the minimum detection limits of the OSL instrumentation. In most instances, these restrictions impose practical lower OSL dating limits on the order of the last few centuries, decades, or even years under favorable bleaching conditions. However, OSL dating uncertainties are often relatively large (>50%) over subdecadal timescales.

OSL dating procedures

OSL samples need to be collected from archaeological sites without exposing them to daylight. This is usually accomplished by hammering opaque PVC or metal cylinders into cleaned sediment sections, excavating sediment blocks, or sampling material at night or during daytime underneath thick opaque sheeting with the aid of filtered lights. In the laboratory, silt-sized or sand-sized quartz/feldspar grains of interest are chemically and physically separated under strictly controlled lighting conditions, and sand-sized

fractions are additionally treated with concentrated HF acid to eliminate their alpha-irradiated outer layers (Aitken 1998).

Once the refined silicate fractions have been isolated, they are mounted on steel or aluminum discs using silicone oil (sand-sized grains), by hand-picking and brushing of individual grains (single-grain measurements), or by settling in acetone (silt-sized grains). The naturally accumulated OSL signals of these aliquots are then measured using specifically designed automated readers equipped with a filtered photomultiplier tube, an array of different LED and laser sources, a controlled heating device and an integrated irradiation source (e.g., Bøtter-Jensen, McKeever, and Wintle, 2003).

Two main approaches are used for determining the D_e value of OSL samples: additive dose and regeneration methods. Both approaches involve calibrating the naturally accumulated OSL signal intensity against a corresponding OSL dose–response curve constructed from different-sized administered doses. In the additive dose method, the dose–response curve is obtained by adding different radiation doses on top of the natural OSL signal for each aliquot or group of aliquots. The D_e value is then calculated by extrapolating the dose–response curve onto the x -axis intercept (Figure 2c). In the regeneration method, the dose–response curve is constructed after first removing the natural OSL signal and sequentially adding known doses to each aliquot or group of aliquots. The natural OSL signal is then interpolated onto the dose–response curve to determine the D_e value (Figure 2b). For both these methods, it is necessary to preheat the sample in order to isolate a thermally stable OSL signal, and to account for any OSL signal sensitivity change arising from repeated heating, OSL stimulation and irradiation (Aitken 1998).

To calculate the environmental dose rate of an OSL sample, it is necessary to determine: (1) the external gamma, beta and (if applicable) alpha dose rate arising from the decay of radionuclides in the surrounding sediment matrix; (2) the internal dose rate contribution from radionuclides found inside the dated mineral grains; and (3) the dose rate from cosmic rays that penetrate through the sediment overburden (Aitken 1985). Three main approaches are used to determine

the external dose rate component in archaeological contexts. The first involves measuring the concentrations of radioactive elements and their daughter products in subsamples of the surrounding sediment using techniques such as inductively coupled plasma mass spectrometry (ICP-MS), X-ray fluorescence, and instrumental neutron activation analysis. The second involves directly measuring radioactive emissions of indicator isotopes in the surrounding sedimentary matrix using techniques such as in situ NaI gamma spectrometry, thick-source alpha counting, low-level Geiger-Müller beta counting, and high-resolution gamma spectrometry. The latter is particularly advantageous in archaeological settings because it permits simultaneous measurement of different parent and daughter radioisotope emissions in the ^{238}U and ^{232}Th decay series, thereby enabling direct assessments of secular equilibrium in the burial environment. The third approach utilizes in situ assessments of luminescence dosimetry capsules that are highly sensitive to radiation exposure (e.g., aluminum oxide and calcium sulphate). Such dosimeters are left buried at the archaeological site for at least several months to provide a reliable measure of the present-day gamma dose rate at each OSL sample position.

The internal dose rate component can be similarly determined using emission counting techniques or assessments of elemental composition (e.g., using electron microprobe or laser ablation ICP-MS analyses of dated grain fractions). Cosmic ray contributions to the environmental dose rate are typically small (<10% of the total dose rate) and are usually estimated using empirically derived equations that take into account site altitude, geomagnetic latitude, and thickness of sediment overburden (Prescott and Hutton 1994). Account must also be taken of long-term sediment water content when deriving the environmental dose rate (Aitken 1985). Interstitial water exerts an attenuating effect on the external dose rate components, since it acts to absorb a fraction of the ionizing radiation that would otherwise reach the quartz or feldspar grains. Typically, the total dose rate for sand-sized quartz grains will vary by ~1% for a 1% change in sediment water content.

Methodological advances in OSL dating

The discovery that OSL could be used as a reliable quartz and feldspar dating tool was first made by Huntley, Godfrey-Smith, and Thewalt (1985), and was closely followed by the discovery that IRSL could also be used to date feldspar samples (Hütt, Jaek, and Tchonka 1988). These breakthroughs built on three decades of thermoluminescence research into establishing “firing event” chronologies for heated materials (ceramics, burnt stones, burnt sediment) and daylight exposure chronologies for unheated sediments. Unlike its progenitor, optical dating utilized only the most light-sensitive electron traps, and it was possible to completely reset the dating signal by relatively short daylight exposures. These advantages significantly reduced the chance of encountering samples with residual luminescence signals at burial, and enabled more reliable dating of archaeological sediments that had experienced shorter daylight exposures.

OSL dating of archaeological sites proliferated during the 1990s and 2000s courtesy of three methodological advances. The first turning point came with the advent of reliable single-aliquot D_e estimation procedures. Early OSL dating approaches required the measurement of large numbers of aliquots (~30–50) to produce a single D_e estimate for a sample. During the 1990s, such multiple-aliquot methods were largely replaced by single-aliquot methods in which all the measurements needed to determine a D_e value are undertaken on a single aliquot. Not only did this avoid problems of variable OSL signal sensitivities from aliquot to aliquot, but it also required less sample material for dating and permitted the generation of replicate D_e populations for each sample.

The emergence of the single-aliquot regenerative-dose (SAR) protocol heralded a second important methodological advance in OSL dating (Murray and Wintle 2000). The SAR protocol incorporated (1) improved D_e precision via interpolation rather than extrapolation of the dose–response curve, (2) a test-dose sensitivity correction procedure to circumvent problems of progressive OSL signal sensitization during repeated laboratory heating, irradiation and bleaching steps, and (3) the provision of several

in-built quality assurance checks on OSL properties, which afforded added robustness to the resultant ages.

The third key advance in OSL dating was the introduction of single-grain OSL techniques, which involved measuring D_e values for individual sand-sized grains rather than individual aliquots containing tens, hundreds, or even thousands of grains. Technological developments in automated single-grain readers during the late 1990s made it practical to measure very large numbers of individual grains in a reasonable amount of time and, thus, to generate statistically significant replicate D_e datasets for each sample. By examining the structure of these single-grain D_e distributions, it is now possible to gain detailed insights into sedimentary complications that might otherwise give rise to multi-grain aliquot OSL age inaccuracies, and to isolate subpopulations of grains that exhibit the most suitable luminescence properties for dating. Single-grain approaches have proved to be particularly advantageous in archaeological contexts, which are apt to suffer from a wide range of bleaching conditions and post-depositional mixing processes (Jacobs and Roberts 2007). The advancement of single-grain OSL dating in archaeological contexts has been further aided by the development of improved statistical techniques for obtaining more representative burial dose estimates from complex D_e datasets (Galbraith and Roberts 2012).

Recent and future developments

Recent developments in OSL archaeological research have focused on extended-range dating signals that display much higher dose saturation limits than the conventional OSL signal. Such extended-range techniques include TT-OSL dating of quartz, single-grain OSL dating of quartz supergrains with very high D_0 values, violet stimulated luminescence dating of quartz, and pIR-IR dating of K-feldspar grains. These approaches offer the potential to extend the traditional upper age limit of quartz OSL by a factor of 2–5, or more (Figure 2d), and to establish archaeological chronologies spanning larger parts of the Middle Pleistocene hominin record. Research is

ongoing to assess the long-term stability of these extended-range signals, and to evaluate their broader reliability across different archaeological contexts using independently dated samples. Existing known-age comparisons of TT-OSL, pIR-IR and supergrain chronologies show good potential for reliable dating over Late and Middle Pleistocene timescales (Arnold et al. 2015). However, these novel approaches are likely to offer the greatest benefit when applied in tandem, and when applied at the single-grain scale of analysis.

Significant advances have also been made using three-dimensional simulations of dose rate environments with Monte Carlo platforms such as Geant4. These modelling frameworks are likely to herald improved reliability in dose rate calculations at archaeological sites exhibiting spatially complex radiation fields, and a better understanding of single-grain D_e scatter arising from beta dose rate heterogeneity.

The next generation of OSL dating research is likely to lie in spatially resolved D_e and dose rate measurements made using photon counting imaging systems and autoradiography interfaces. Several custom-built and commercially available EM-CCD systems have been developed for spatially resolved OSL dating purposes over the last few years. Efforts are now focused on improving hardware and data processing capabilities, and establishing reliable and precise methodologies for in situ OSL dating of intact sediment slices.

Dating Ceramics and Luminescence

JAMES K. FEATHERS

University of Washington, USA

Luminescence dating of ceramics was first introduced in the late 1970s (Aitken 1985). Only in the last 20 years has its use become widespread, partly because of methodological developments that have increased its precision. As a direct method of dating heating events, it has been able to address some chronological problems in ceramic studies that were not feasible before.

Introduction

Use of ceramic style to construct archaeological chronologies has a long and mostly successful history, but such use is restricted to ordinal scales and is not always easy to apply to individual ceramics. The promise of ratio scale (absolute) dates for ceramics was first realized in the 1970s and 1980s by the development of luminescence dating. More recently, radiocarbon dating has been applied to ceramic residues and to temper. While this has great potential in selected applications, it is plagued by association problems linking the age of ceramic manufacture with the radiocarbon age. Another new development is dating ceramics using rehydration rates, but this method still requires additional research. Luminescence has the advantage of a close match between the manufacturing age and the event dated by luminescence, which is the last exposure to sufficient heat (or light). It works on ubiquitous materials, quartz and feldspar, which are found in most ceramics, making it one of the most widely applicable dating methods in archaeology.

While it has often been used as a second choice to radiocarbon dating, where radiocarbon-datable materials are either unavailable or unreliable, such usage, for example, in trying to date features which contain ceramics,

may have the same association problems as radiocarbon, depending on the target event. Rather, the most singular value of luminescence is its ability to date manufacturing events directly. It can thus be used to measure technological change, isolate different components of mixed assemblages, and assess occupation duration. Beyond pottery, it can be applied to many structural materials such as bricks, adobe, daub, and burned clay (see a recent review by Bailiff 2014).

Technical aspects

Luminescence is based on the ability of some minerals to store absorbed energy from natural radiation for lengths of time much longer than the history of ceramics. This energy, stored as ionized particles trapped in crystalline defects, is released upon heating or exposure to sunlight, producing a luminescence signal. The intensity of this signal is proportional to the time since last heating or light exposure. The accumulated dose (or paleodose) can be measured as luminescence either by heating the sample (thermoluminescence, or TL) or by exposing the sample to a narrow wavelength of light (optically stimulated luminescence, or OSL). Calibrating the sensitivity of the signal against laboratory irradiation (resulting in an equivalent dose, D_e), and dividing by the dose rate (the amount of irradiation received by the sample per unit time) yields an age. With some exceptions, the dose rate does not change significantly through time. Historically, ceramics were dated by TL, but in recent years, most dating has been done by OSL, although TL is still used.

The dose rate comprises alpha, beta, and gamma radiation, with some contribution from cosmic radiation. These kinds of radiation have different effective ranges. Alphas range up to 20 μm , betas up to 3 mm and gammas up to 30 cm in ceramics or sediment. The cosmic range is even greater yet, but is usually barely significant. When sampling the ceramic, if the outer 2 mm are removed or avoided, then the luminescence

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0153

of the ceramic will be a function of alphas and betas from only the ceramic itself, gammas from the ceramic and the surrounding sediment, and cosmic radiation. Thus to determine the total dose rate, it is necessary to measure not only the radioactivity of the ceramic, but also of its immediate surroundings. Gamma dose rates can be measured in the field, but this is rarely done for ceramics because these surroundings are often destroyed during excavation. Rather, a sample of the surroundings is collected and sent to the laboratory for measurement. The more complicated the surroundings (which might include rocks, other artifacts, architectural remains, and organics as well as sediment), the more difficult it is to determine a precise gamma dose rate. Fortunately, in many, but by no means all, situations, radioactivity across a site does not vary much. Sometimes archaeologists want to date ceramics but have no sediment sample, for example, with museum specimens. This can be done if reasonable approximations of the external dose rate can be made, although at a cost of precision.

In terms of which minerals in a ceramic to date, there are two options. The first option is to date coarse-grain (90–250 μm) inclusions. Most often, quartz inclusions are isolated. While feldspars may also be used, heating tends to increase the sensitivity of quartz while reducing the sensitivity of feldspars. Feldspars also suffer from an athermal loss of signal through time called anomalous fading. Fading can be corrected for, but only at a cost of precision. Quartz is therefore usually preferred unless it is absent or of particularly low sensitivity. The other option is to date polymineral fine grains (1–8 μm). This has some advantages. First, ceramics often do not contain sufficient numbers of coarse grains, and, second, fine-grain dating is less dependent on external dose rate. In coarse-grain dating, the inclusions lack a source of short-range alpha irradiation. While this avoids special problems with alpha irradiation, it means the dose rate is dominated by beta and gamma radiation. Betas arise from the ceramic itself (if the outer 2 mm is removed), but gammas, which can make up as much as half the dose rate, come from the immediate surroundings. If ceramics come from complex environments, estimating the gamma dose rate can be difficult and error-prone. With fine-grain analysis, however, the alpha

contribution has to be considered along with the betas and gammas, the gammas now only contributing about a quarter of the total dose rate, allowing more tolerance in their uncertainty. The disadvantage of fine-grain analysis is the difficulty in removing feldspars from the sample, and anomalous fading must be taken into account.

To determine D_e by TL, multi-aliquot methods are normally employed. The two most common are called additive dose (where different laboratory doses are added to the natural doses of several aliquots to form a growth curve plotting dose against TL, and D_e is determined by extrapolation) and regeneration (where laboratory doses are applied to aliquots which have been zeroed by heat and the natural signal is interpolated into a subsequent growth curve to determine D_e). Both methods have problems with sensitivity changes, which can be minimized by combining both methods in what is called the slide method. For fine-grain samples, the TL signal has to be corrected for fading. D_e from OSL is usually determined for coarse grains by the single-aliquot regeneration (SAR) method (Wintle and Murray 2006), which uses test doses of equal magnitude to correct for sensitivity changes brought about by successive irradiation, preheating and stimulation. Because D_e is determined on just one aliquot, precision is improved (obviating any need to normalize among aliquots) and it also becomes possible to measure multiple aliquots to document any variation in D_e that might be present, due to uneven heating or heterogeneity in the distribution of radiation sources (mainly from betas), among other causes. Scanning equipment to measure D_e from individual grains within a ceramic slice has been used to detect spatial variation in D_e to the same effect. Future research promises to couple some kind of scanning equipment for luminescence with a method for detecting differential dose rate (e.g., placing a sheet of $\text{Al}_2\text{O}_3:\text{C}$, a powerful dosimeter, across the slice). Different ages for different parts of the ceramic could then be obtained.

For fine-grained samples, a “double” SAR has been developed, where infrared stimulation (IRSL) precedes each OSL stimulation (usually with blue light). Feldspars, unlike quartz, are sensitive to IRSL, and are also the main sources of anomalous fading. The rationale is that the

preceding IRSL will reduce the feldspar signal, so that the subsequent OSL will be dominated by the contribution from quartz, and thus not fade. This is particularly the case where original heating of the ceramics has reduced the feldspar sensitivity while increasing that of quartz. Nevertheless, feldspars are also sensitive to OSL, and in some samples, the IRSL will not remove the feldspar signal, so that feldspar contributes to the subsequent OSL, which may then be subject to fading. The OSL may then only provide a minimum age unless fading is corrected (a time-consuming process). Another way to gauge whether the OSL signal is mainly coming from quartz is to measure the *b*-value. This is a measure of alpha efficiency (another method is called *a*-value). Because of their short range, alphas do not travel far enough for all of their energy to get absorbed as trapped charge. Thus they are less efficient at producing luminescence than betas or gammas. The *b*-value compares the sensitivity of the sample to alpha and beta irradiation (the latter about 10 times more effective), and uses this ratio to correct the alpha dose rate. The *b*-value for quartz ranges between about 0.4 to 0.7, while the *b*-value for feldspar is much higher. Measuring the *b*-value for OSL provides one indication of whether the OSL signal is dominated by quartz or not, and thus the likelihood of fading. Often both TL and OSL are measured. This is because OSL sometimes produces unreasonably old ages. While the cause is uncertain, it may be because the OSL fast bleaching component was either originally absent or destroyed during original heating, so that only a slow bleaching component remains, and this may not have been reset by the original heating. Obviously, where agreement in age between OSL and TL is obtained, the highest confidence can be placed in the age.

Some ceramic sherds pose difficulties in dating, usually because of the absence of suitably sensitive minerals. Ceramics from volcanic regions, for example, are often problematic, the Pacific Islands being a prime example. The feasibility of measuring volcanic quartz with TL using red emission (as opposed to the usual blue emission), however, has been demonstrated on Japanese pottery.

Aside from these exceptions, however, many sherds are datable, and to a precision often better than 10%. In terms of accuracy, a simulation study

showed that with quartz dating of pottery, D_e values obtained on given burial doses could achieve an accuracy of better than 10%. Fewer empirical comparisons have been done systematically, although many studies show ceramic dates to agree with independent evidence in most cases. A comparison of results between two laboratories on 25 sherds from North Carolina showed some divergences, mostly because of different procedures followed, but the results from either lab agreed broadly with independent chronological evidence. The study shows that dates are not just numbers from a black box, but estimations that need evaluation both from the luminescence and the archaeological perspective.

Applications

Many requests for dating ceramics that come into the University of Washington laboratory, a major provider of ceramic dating, reflect luminescence as a second choice because material for radiocarbon dating was not available, had association problems for the event of interest, or provided low precision because of flatness in the calibration curve. Yet there are chronological problems where luminescence should be the first choice, rather than something turned to because other dating is not viable. Such applications are the focus in this section.

For time periods when ceramics form a large portion of the archaeological record, the smallest unit of analysis, in some sense, is the ceramic sherd. Knowing the manufacturing date of each sherd could provide a wealth of information of archaeological interest, but of course would be prohibitively expensive. Projects dating 30–40 ceramic sherds have been performed, but even smaller numbers could potentially yield useful information given prudent sampling. For example, in testing whether different sites in the Lower Mississippi valley overlapped in their durations, one study sampled from just one stylistic type to see if the presence of that type among the sites was chronological or just represented spatial interaction. A sample of 10, while still small, was able to answer the question. In a similar vein, another study used luminescence to date particular stylistic types to show that pueblos in New

Mexico may have been abandoned much later than was suggested by tree-ring dating (which dates a different event). Using luminescence to address occupation issues, however, assumes that the time between manufacture (the event luminescence addresses) and discard is relatively short, which is often the case with cooking ware. There are cases where this time could be long, as in the case of heirlooms. Ceramic inhaling bowls on the Caribbean island of Carriacao were found by luminescence to be several hundred years older than the earliest radiocarbon dates on the island.

All archaeological sites are to some degree palimpsests: time-averaged mixtures of artifacts deposited at different times. A key object of archaeological research is to separate these palimpsests into temporally distinct components to the extent possible. Luminescence provides one solution to this problem for ceramic-bearing sites. One study showed that large enclosure pits in the UK contained ceramics dating to a wide range. The larger the pit, the more likely this was the case. Another study found that ceramics from pits in an Illinois site date to a much wider range than radiocarbon dates (based on combined charcoal pieces) suggested, resolving some typological issues of whether certain types had longer temporal ranges or not. At a regional scale, luminescence can help determine whether different sites are the same age or not. For example, in Arkansas, luminescence showed that small “farmsteads” pre-dated the occupation of large centers.

Sherds may not be the only datable material. Monumental architecture is often composed of bricks (fired, or unfired as in the case of adobe). Dating individual bricks can be a way of determining different stages of construction, evidence of repair, and repeated use of old bricks (Bailiff 2007). Other ceramic material, such as mortar, can be dated. While somewhat off the topic of this article, luminescence has long been applied to burned lithics, including fire-cracked rocks, so these too can serve as basic dating units.

Tracing technological change is challenging in archaeology, partly because of the reliance on similarity-based dating techniques, such as seriation and ceramic cross-dating, or on stratigraphy, both anchored by radiocarbon or some other dating method. The target event for these methods is usually the occupation, to which an assemblage of artifacts is assigned. Such dating

sets up boundaries between assemblages (often referred to as phases) and puts emphasis on discontinuities rather than the continuous nature of change. This makes change seem transformational. First one kind of ceramic was made, then another. Change is more likely selectional, where the frequencies of different kinds of ceramics change through time. One ceramic type increases at the expense of another. This kind of change might be measurable if the target is the date of manufacture rather than the occupation. This was demonstrated by Feathers (2009), who was looking at the rise of shell-tempered pottery in the southeastern US. In northern Alabama, the conventional wisdom is that shell-tempered pottery rather abruptly replaced grog-tempered pottery, with some overlap at “transitional” sites. Luminescence dating of individual sherds, however, showed that some shell-tempered pottery appeared quite early and some grog-tempered pottery appeared quite late, so the change was a change in frequency, not an abrupt introduction of shell-tempered pottery.

Dating Pollen

WILLIAM J. FLETCHER
University of Manchester, UK

Introduction

Pollen grains, the male microgametophytes of seed plants (angiosperms and gymnosperms), are widely distributed in the environment and accumulate in a range of sedimentary environments including lakes, bogs, caves, floodplains, and the deep oceans. While some components of pollen grains such as the generative nucleus degrade quickly in the environment, the resilient pollen wall can be preserved for thousands to millions of years. The widespread distribution and high preservation potential of pollen grains underline the value of ancient or “subfossil” pollen not only as a tool for reconstructing past vegetation history and environmental change (see *PALYNOLOGY*), but also as a sample material for radiocarbon dating. The wide variety of deposits that have been successfully dated from pollen include peats, lake sediments, aeolian deposits, packrat middens, and Pleistocene ice-wedge casts. Key advantages of pollen as a dating material are that it may be present in deposits where plant macrofossils are scarce or lacking, and it can be identified in terms of the source vegetation, unlike bulk material where the provenance is unknown.

Basis of the approach

Pollen grains, along with the spores of terrestrial lower plants (ferns and mosses), possess several characteristics that make them highly suitable for radiocarbon dating. The pollen wall is composed of the organic biopolymer sporopollenin, which is rich in carbon in the form of both long-chain macromolecules and aromatic compounds. Carbon in sporopollenin is derived from atmospheric CO₂ through photosynthesis, incorporating photosynthates that are either

newly acquired during the pollen development stage or derived from stored reserves of at most a few years' age (e.g., Davis and Sparks 1971). Pollen grains therefore provide a reliable and effectively instantaneous “snapshot” of carbon isotopic ratios in the atmosphere during the time of pollen development. Fractionation effects (differential uptake of heavy and light carbon isotopes) occur during photosynthesis, but these are assessed by the parallel measurement of radioactive (¹⁴C) and stable (¹³C) carbon isotopes and are corrected for in the reporting of radiocarbon dating results. Sporopollenin is furthermore remarkably resistant to chemical attack, meaning that pollen grains are inert in the environment and can be considered closed systems with respect to the pool of carbon within them. Finally, the morphological characteristics of pollen grains mean that they can be identified to different taxonomic groups (typically families, genera or species), providing valuable contextual information for the dated sample.

Preparation procedures and practical considerations

Dating of pollen requires the preparation, in a suitably equipped laboratory, of a pollen-rich organic residue or pollen concentrate. This process shares many stages with the preparation of pollen residues for microscopic analysis, while avoiding carbon-containing chemicals (e.g., acetic anhydride, used in acetolysis, and ethanol). Typically, a combination of digestion stages in acidic and alkaline reagents is used to remove carbonates and humic acids from the peat or sediment sample, followed by deionized water washes to remove clay particles. Finally, the concentration of pollen grains is achieved through separation of the organic fraction using dense media (heavy liquids) and microsieving. Dense media separation may either be undertaken at a single target density (e.g., 1.5 times the density of water, or 1.5 SG) in which pollen grains, which have a typical density of slightly less than 1.5 SG

(Régnell and Everitt 1992), float, or at a series of decreasing densities (e.g., from 1.6–1.15 SG), allowing selection of the purest residue(s) for dating (Vandergoes and Prior 2003). Alternatives to density separations include manual selection of individual grains using a micromanipulator (e.g., Long, Davis, and De Lanois 1992), and isolation of pollen grains using flow cytometry (Tennant et al. 2013). However, the former technique is generally too time-consuming to be practical unless very large pollen grains such as *Picea* are abundant, and the latter has yet to be routinely applied for radiocarbon dating. Sieving using nylon mesh can be used to further concentrate organic particles within the size range of pollen (typically ~20–80 µm, but this may be tailored to suit the predominant pollen types in a specific sample) (Brown et al. 1992).

At each stage of the preparation, it is helpful to inspect the content of the residue under a high-powered transmitted light microscope, using a fine Pasteur pipette to extract a minute droplet of residue and placing it on a microscope slide under a coverslip. This allows the efficacy of the preparation stages to be assessed and modifications to be implemented as necessary, for example in selecting suitable sieve mesh apertures with respect to the size classes of both target pollen types to be retained and any undesirable organic components to be removed. Visual inspection and quantitative estimation (e.g., tally count of objects) of the purity of the pollen concentrate is essential, since the efficacy of the pollen concentration preparation may be strongly influenced by site- and sample-specific characteristics including total pollen concentration in the deposit, as well as the composition and proportions of different organic matter types (pollen, terrestrial plant spores, algal spores, fungal spores, microcharcoal, wood fragments, leaf tissues, etc.).

Particular attention must be paid to maintaining a clean working environment and avoiding contamination with modern carbon in the form of ambient dust, pollen, powders, oils, and so on. This does not require the use of a certified clean-room facility, but simply special attention to minimizing exposure to contaminants by common-sense means, including wearing powder-free gloves at all stages, working with capped centrifuge tubes, pre-cleaning glassware

and foil by heating to 500°C in a furnace, and thoroughly rinsing plastics (tubes, mesh, etc.) in deionized water. In light of the small sample size of pollen concentrates and the fairly intense pre-treatments required, it is advisable to undertake the parallel processing and dating of one or more laboratory standards to rule out contamination with modern carbon and to allow for correction factors to be applied if necessary. In any case, it is advisable to discuss the strategy for pollen concentrate dating with the radiocarbon facility prior to undertaking the preparation procedure.

Pollen concentrates should be dried or freeze-dried prior to measurement of the dry weight of sample submitted for dating. Advances in the measurement of small samples and widespread availability of the AMS technique mean that samples containing as little as 200 µg of carbon may be dated at many globally distributed radiocarbon facilities, and even smaller samples may be dated at some facilities. When assessing the size of samples for analysis, it should be taken into account that the pollen concentrates may not be composed entirely of pollen, and that pollen itself is only composed of around 50% carbon. In practice, dry sample weights of around 5–15 mg are recommended. While these amounts are small, quite large quantities of starting material may be required to produce pollen concentrates of sufficient size. At the outset, it is helpful to know the absolute concentration of pollen in the sediment sample, as commonly estimated through the addition of an exotic marker such as *Lycopodium* spores. This approach, of course, cannot be used *directly* in the exact sample to be dated. In a recent case study, approximately 15 g of dry lake sediments with a typical pollen concentration of ca. 200,000 grains per cm³ were used to generate pollen concentrates ranging from 1–9 mg dry weight and 48% carbon content (Fletcher et al. 2017). Higher, or lower, pollen concentrations in the material would allow for smaller, or demand larger, starting samples, respectively.

Interpretation of pollen dates

In common with all dating approaches, attention should be paid to the characteristics of the sample material when interpreting the results of the radiocarbon dating. In principle, a sample of pollen grains should not be subject to uncertainty associated with dating samples from long-lived organisms, such as wood or charcoal, in which carbon accumulates sequentially over considerably longer timescales (decades to centuries). In practice, however, a sample of ancient pollen extracted from a sedimentary deposit will typically integrate pollen released over multiple seasons of pollen production, depending on the sedimentation rate of the deposit. Nevertheless, the resulting age of the pollen concentrate should provide an accurate estimate of the time of incorporation of pollen into the deposit. In the context of a continuously accumulating deposit, the age of the pollen concentrate will therefore indicate the time of deposition and provide a suitable basis for the development of depositional models and estimation of sedimentation rates. Two potential sources of uncertainty should be considered, namely reworking of old pollen from soils or sediments (e.g., Howarth et al. 2013), and incorporation of organic matter derived from aquatic production in deep lakes and hardwater settings (e.g., Fletcher et al. 2017). Both problems may result in ages that are older than the time of deposition, due either to the incorporation of non-contemporaneous (old) pollen grains, or contemporaneous organic matter containing old carbon associated with aquatic reservoir effects (MacDonald, Beukens, and Kieser 1991). The best guard against misinterpretation is good knowledge of the composition of the dated sample derived from visual inspection of the pollen concentrate prior to dating, accompanied by good contextual (geological, geomorphological, hydrological) information about the site. Comparison of the pollen concentrate ages and other dating results, such as radiocarbon dates on terrestrial plant macrofossils where available, can be highly

informative regarding the detection of reworking or reservoir effects.

Dating Rock and Desert Varnish

TANZHUO LIU

Lamont-Doherty Earth Observatory of Columbia University, USA

Introduction

Desert varnish, or rock varnish in general, is a slow-accreting (1–40 $\mu\text{m}/\text{ky}$) manganese–ferrous dark coating on subaerially exposed rock surfaces (Perry and Adams 1978; Dorn and Oberlander 1981; Liu and Broecker 2000). It often reaches a typical thickness of 50–200 μm when fully developed (Figure 1a). Although formed in nearly all kinds of climatic settings, varnish is mostly seen in arid to semiarid deserts of the world. It comprises up to two-thirds of clay minerals, a quarter of manganese (Mn) and iron (Fe) oxides, plus several dozen minor and trace elements. Mn is typically enhanced over Fe more than by a factor of 50 above potential source materials such as dust, soils, water, and the underlying rock (Figure 1c). Three hypothetical models have been proposed to reconcile the enrichment of Mn in varnish formation (Dorn 2009). The biotic model posits that microbial agents colonizing rock surfaces preferentially fix Mn in accreted clays from desert dust. The abiotic model states that Mn enrichment is a physicochemical process involving mobilization from desert dust by pH-Eh fluctuations and precipitation events. The hybrid model claims that varnish formation is attributed to a combination of processes, where slow-growing bacteria fix Mn and Fe, which are then abiotically cemented by clay minerals. Despite decades of extensive research on the subject, the real mechanism of varnish formation is still poorly understood. One thing is, however, clear: its source materials come largely from airborne dust and dew rather than from the weathered substrate rock. This fact points to microscale sedimentary processes involved in the varnish deposition on rock surfaces.

Because of its sedimentary origin, varnish contains a laminated microstratigraphy that records past environmental fluctuations, especially wetness variations (Figure 1b). In the Great Basin of the western United States, Mn- and Ba-poor varnish layers, which are orange-yellow in ultrathin sections (5–10 μm thick) under transmitted polarized light, were formed during the overall dry period of the Holocene; Mn- and Ba-rich dark layers were deposited during the last glacial period when the Great Basin was much wetter than it is at present (Broecker and Liu 2001; see Figure 1b–c). Wet events represented by the glacial-age dark layers in the western US varnish correlate in time with cold episodes of the Younger Dryas (YD) and Heinrich events (H1–H6) in the North Atlantic region (Liu et al. 2000; Liu and Broecker 2007). Fine-grained and fast-accumulating varnish also records late Pleistocene and Holocene millennial-scale wet events synchronous with millennial-scale cooling events in the North Atlantic and Greenland (Bond et al. 1997, 1999; see Figure 2). These findings give rise to the use of varnish laminations (VML) as a dendrochronology-like age-dating tool.

Principle and method

The basic premise of VML dating rests on an empirical observation that the formation of varnish microstratigraphy is generally tied to regional and global climatic variations: Mn- and Ba-rich dark layers formed in relatively humid periods, while Mn- and Ba-poor orange-yellow layers formed in relatively dry periods. Because climatic signals recorded in varnish are regionally and globally contemporaneous, once radiometrically calibrated and climatically correlated, VML can be used as a correlative dating tool to yield minimum-limiting surface exposure ages for varnished geomorphic and geoarchaeological features in the world's deserts. A rigorous blind test of this method was conducted on late Pleistocene lava flows in the Mojave Desert, California (Liu 2003; Phillips 2003). The convergence between cosmogenic ^{36}Cl ages and VML age estimates for

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0157

three basalt flows in the Pisgah, Cima, and Amboy volcanic fields demonstrates that VML is a valid geochronological tool (Marston 2003). Recent studies (Liu and Broecker 2007, 2008, 2013) extended the VML dating potential to ~ 300 ka.

VML dating starts with varnish sample collection in the field. Because varnish accretes in a time-transgressive fashion within millimeter-sized microbasins on subaerially exposed stable rocks, the oldest possible varnish on a given

Figure 1 (a) Desert varnish formed on a ~70 ka desert pavement surface in Death Valley, California. (b) Visual microstratigraphy seen in varnish ultrathin section under a microscope with transmitted polarized light. (c) High-resolution ($128 \times 128 \mu\text{m}$) electron microprobe elemental mapping of manganese (Mn) and barium (Ba) abundance in desert varnish from Death Valley. The mapped area is framed in image (b) and the color scale of elemental concentration is shown on the right side of each panel. The zigzag curve depicts the probe line profiling for Ba. LU-1 to LU-5 represent five layering units (LU) recognized in the generalized master layering sequence for the western US drylands, and WP0–WP6 denote seven Mn- and Ba-rich major dark layers, interpreted to represent seven major wet periods during the last glacial time. These periods correlate in time with the cold episodes of the Younger Dryas (YD) and Heinrich events H1–H6. The Mn- and Ba-poor surface top layer (LU-1) and basal layer (LU-5) represent periods of dry climate during the Holocene and the last interglacial, respectively. rock surface should be collected to maximize the chance of getting VML age estimate close to the surface exposure of the dated rock. This way of sampling is, however, experience-dependent and needs years of training and practice in the field. To sample surface geoarchaeological features such as stone artifacts and petroglyphs, a battery-driven mini-dremel attached to a diamond-coated drill bit is often used to acquire a 3-mm-long and 4-mm-sized mini-core that hosts the oldest varnish-filled microbasin. The sampled spot may be visually restored by inserting a varnish-coated mini-core of similar size from nearby rock of the same lithology.

In the lab, ultrathin sections of varnish-retained mini-cores are made using an innovative thin-sectioning technique, which permits examination of varnish microstratigraphy (Liu and Dorn 1996). The conventional way of making varnish thin sections cannot be employed, because the resulting sections are too thick (25–30 μm) and do not reveal visual microstratigraphy, which is opaque in normal geological thin sections. Varnish ultrathin sections are then photographed using a Leica DMLB light microscope equipped with a Leica MPS 60 Photoautomat system. Polarized light is used to increase image contrast. The use of a 10 $\times$ eyepiece in combination with a 40 $\times$ objective lens yields images with 400 $\times$ magnification of varnish microstratigraphy for layering pattern analysis. Electron microprobe is also used to acquire high-resolution (~2 μm) elemental mapping and line profiling of varnish microstratigraphy. These chemical data allow quantitative characterization of Mn, Ba, and other elemental fluctuations in varnish

microstratigraphy and assist in layering pattern interpretation.

Radiometric age calibration of a generalized master layering sequence constitutes the most difficult task in VML dating. Because of the limitations of available radiometric means such as radiocarbon and cosmogenic radionuclide methods, direct dating of individual layers in varnish microstratigraphy is not yet possible. The only feasible approach at present is collecting varnish from a geomorphic surface of known age and using this age as a maximum-limiting time constraint for initial deposition of the basal layer in varnish microstratigraphy (Liu and Broecker 2007). In addition, there is an unknown lag time between the surface exposure of a rock face and the subsequent varnish initiation on it, which often introduces uncertainties in the radiometric age calibration of the varnish layering sequence. New studies (Liu and Broecker 2018) indicate that, under favorable conditions, about 100 years or fewer may be needed for the very first varnish to initiate on subaerially exposed stable rock surfaces in arid to semiarid deserts. This finding suggests that, by deliberately sampling the oldest possible varnish on a well-dated surface, it is possible to reduce the lag time-related uncertainties in age calibration of the varnish layering sequence to about 100 years.

Climatic correlation of the wetness variations recorded in varnish microstratigraphy is critical for VML dating, which determines its intrinsic age resolution and regional applicability. Paleoclimate studies (Bond et al. 1997, 1999) indicate that the late glacial and Holocene climate history of the Earth is characterized by rapid, millennial-scale

Figure 2 A generalized late glacial and Holocene varnish layering sequence in the drylands of the western United States and its climatic correlation with the GISP2 ice core record. Wet events recorded as dark layers (WP0a, WP0+a, WP0+b, WP1a–d) in the varnish-layering sequence correlate in time with cooling events represented by oxygen isotopic troughs (labeled a–c, a–b, a–d) in the GISP2 ice core record. Also included in this diagram is the climatic correlation of Holocene wet events (WH1–WH12) in the varnish record with Holocene cooling events (LIA, 1–8) in the North Atlantic deep-sea sediment records. Age assignments for dark layers in the varnish record are derived from the depicted climatic correlation (see Liu and Broecker 2007, 2008). The grayscale shading represents relative concentrations of Mn and Ba in varnish microstratigraphy. The North American archaeological periods or intervals are plotted against the varnish layering sequence for comparison: Post-Archaic (0–3 ka); Archaic (3–10 ka); Clovis (12.9–13.2 ka); Paleoindian (10–20 ka). LU = layering unit; WP = wet event in Pleistocene; WH = wet event in Holocene; H = Heinrich event; OLD = Oldest Dryas; IACP = Intra-Allerød Cold Period; YD = Younger Dryas; LIA = Little Ice Age.

fluctuations. The most prominent of such climatic oscillations are the Heinrich event H1, the Intra-Allerød Cold Period (IACP), the YD cold reversal, and Holocene millennial-scale cooling events. All these climatic oscillations happened nearly synchronously around the globe and left their imprints in various geological records such as polar ice cores, deep-sea sediments, and cave deposits and have been well dated by radiometric means. When spatially and temporally correlated, they provide accurate age references for the associated wetness variations archived in the varnish record (see Figure 2).

Application and limitation

Once radiometrically calibrated and climatically correlated, the master varnish layering sequence can be used as a correlative dating tool to estimate numerical ages for surface geoarchaeological features in drylands (Figure 3). In northern New Mexico, near a small town of Chili, a grinding stone (or metate) is coated with incipient spotty varnish (Figure 3a). The presence of numerous Anasazi pottery shards (Pueblo II–III pottery) at the sampling site indicates occupation of the place by the Anasazi Indians around 0.7–1.1 ka. Varnish from the metate displays a latest Holocene layering sequence of LU-1 (WH2) with basal dark layer WH2 (Figure 3b). Given the age scale of the master layering sequence established for the western United States (Figure 2), this yields a VML-based age estimate of 0.9–1.1 ka for the deposition of basal dark layer WH2. Since the WH2 deposition postdates the abandonment of the metate, the varnish age estimate suggests occupation of the site by the Anasazi Indians around 1.0–1.2 ka (assuming 100 years of varnish lag time), a result consistent with the pottery evidence. In the Mojave Desert of eastern California, a curvilinear petroglyph was pecked by ancient humans on a basaltic bedrock surface (Figure 3c). Varnish from the petroglyph grooves displays an early Holocene layering sequence of LU-1 (WH10), yielding a VML-based age estimate of 9.4 ka for the deposition of basal dark layer WH10, and thus 9.5 ka for the pecking event (Figure 3d). In Ocotillo of southern California, varnish from the flaked face of a primary core

displays a latest Pleistocene layering sequence of LU-2 (WP0a), yielding a VML-based age estimate of 11.75 ka for the deposition of basal dark layer WP0a and 11.85 ka for the flaking event (Figure 3e–f). This age estimate suggests occupation of Ocotillo by the Paleoindians during the terminal Pleistocene.

Like any other surface exposure dating techniques, VML dating has inherent limitations that hinder its chronometric application. First of all, VML dating relies largely on layering pattern interpretation of varnish microstratigraphy, which is experience-dependent and requires years of training and practice. Second, making varnish ultrathin sections plays a vital role in VML dating, which is also skill-dependent. Ultrathin sections that are well polished yield high-resolution images of varnish microstratigraphy, thus reducing ambiguities in layering pattern interpretation. Third, varying rates of varnish accretion over time create complexities in layering pattern interpretation. Fourth, not every varnish-filled microbasin contains a laminated microstratigraphy for layering pattern analysis. Large-grained and detritus-rich materials in varnish do not facilitate the formation of microlaminae. Postdepositional modifications such as chemical leaching and bioturbation may alter originally layered microstratigraphy. One simple way to avoid or minimize these uncertainties in VML dating is making three (or more if possible) varnish ultrathin sections for each sample and choosing the most unambiguous and oldest layering sequence for layering pattern interpretation and age estimate.

Conclusion

Although still experimental in nature, VML dating is a conservative age determination tool that yields minimum-limiting surface exposure ages for dated rocks. Laminated microstratigraphies exist in varnishes from warm and dry deserts of the world, including the Negev Desert of the Middle East, the Gobi Desert of western China and Mongolia, the Atacama Desert of South America, and the Sahara Desert of Africa. These desert regions host numerous sites of ancient petroglyphs, geoglyphs, and surface stone artifacts.

Figure 3 VML dating of petroglyph and stone artifacts in the drylands of western USA. *Upper panel:* A grinding stone is coated with incipient spotty varnish in northern New Mexico (a). Microstratigraphy in the varnish (b) displays a latest Holocene layering sequence of LU-1 (WH2), yielding a VML-based age estimate of 1.0–1.2 ka for site occupation by the Anasazi Indians. *Middle panel:* A curvilinear petroglyph is coated with patchy varnish in the Mojave Desert of eastern California (c). Microstratigraphy in the varnish (d) displays an early Holocene layering sequence of LU-1 (WH10), yielding an age estimate of 9.5 ka for the pecking event. *Lower panel:* A primary core is coated with well-developed patchy varnish in Ocotillo of southern California (e). Microstratigraphy in the varnish (f) displays a latest Pleistocene layering sequence of LU-2 (WP0a), yielding an age estimate of 11.85 ka for the flaking of this stone artifact by the Paleoindians. Arrows in the images point to spots where varnish-filled microbasins were cored with a mini-dremel for VML analysis.

Radiometric age calibration and climatic correlation of the varnish wetness records in the regions have been underway. Once they are completed, VML dating will have the potential of providing millennial-scale age estimates up to ~74 ka for surface geoarchaeological features in the world's deserts.

Magnetostratigraphy

GIOVANNI MUTTONI

Università degli Studi di Milano, Italy

Theory

Magnetostratigraphy deals with the recognition in a rock succession of the stratigraphic levels in which the polarity reversals of the Earth's magnetic field are recorded. Units of homogeneous (normal or reverse) polarity are called magneto-zones, while their correlative time intervals are called Chrons.

The Earth's magnetic field is generated in the outer core by the convection of electrically conducting liquid iron alloys driven by compositional and thermal buoyancy forces. These cause the fluid to rise or sink while being deflected by the Coriolis effect into helical structures that through magnetic induction continuously generate an essentially dipolar field (~90% of the total field) accompanied by nondipolar structures that vary over secular timescales. The geocentric dipole axis, when averaged over a few thousand years, becomes aligned along the Earth's rotation axis (Langereis et al. 2010).

The Earth's field possesses two polarity states, normal and reverse (Langereis et al. 2010, Figure 1), which can flip with no predicted periodicity. This random character confers stratigraphic value to magnetic polarity reversals. A reversal typically takes a few thousand years (or less) to occur, a process fast enough to generate globally synchronous time lines useful for correlating distant sedimentary or volcanic sequences. Dating is possible by correlating a magnetozone sequence to a radiometrically and/or astrochronologically dated geomagnetic polarity timescale (GPTS; see below). The polarity reversal frequency has increased from nil between 121 and 83 Ma in the Cretaceous (when the field maintained stable normal polarity) to around 5 per Ma over the course of the Cenozoic.

There exist natural processes that are able to register direction and intensity of the ancient geomagnetic field in rocks at the time of their formation. Rocks commonly contain magnetic minerals, for example magnetite and hematite. These minerals form in magmatic rocks by exsolution from solid solutions and acquire ferromagnetic properties upon cooling below their Curie temperatures (e.g., ~580 °C for magnetite). Once eroded and transported, they can also get incorporated in sediments by means of gravitational settling. Also, magnetotactic bacteria can biomineralize micrometric magnetite grains that can become incorporated in sediments. These magnetic minerals may be comprised of one or more magnetic domains, volumes characterized by an intrinsic magnetization at saturation. In the case of single domain grains, which typically carry a stable magnetization, this magnetic moment is aligned along preferred directions dictated by the grain shape or crystallographic axes.

During magma cooling to below the Curie temperature(s), or sedimentary settling of particles, these magnetic moments statistically align with the ambient geomagnetic field and are subsequently "locked" in the rock by further cooling or lithification processes, thus recording the direction of the field as thermoremanent magnetization (TRM) or detrital remanent magnetization (DRM), respectively. Post-depositional realignments of magnetic particles in the water-saturated topmost layer of the sediment can produce a post-depositional DRM. Compaction and dewatering then mechanically fixate the aligned particles, preserving the direction of the ambient field. A chemical remanent magnetization (CRM) is instead acquired when a magnetic mineral grows through a critical blocking volume at which the ambient field is again locked-in against thermal disorder. In all these cases, the generated primary magnetization can be stable for billions of years or until the rock is weathered or thermochemically altered, causing the original magnetization to be variably overprinted by a secondary magnetization.

Figure 1 The Lourens et al. (2004) timescale (ATNTS2004) for the last 6 Ma tied to Pliocene–Pleistocene stages. Subchrons are as follows: J = Jaramillo; CM = Cobb Mountain; O = Olduvai; R = Reunion; K = Kaena; M = Mammoth; C = Cochiti; N = Nunivak; S = Sidufjall; T = Thvera (ages in main text and in Lourens et al. 2004). T = Tarantian; L = Late.

Methodology

Samples are taken in the field with an electric or gasoline-powered drill and oriented relative to the north and the horizontal plane with a magnetic or sun compass mounted on a specific orienting device. Core samples are then reduced to approximately 10-cc cylinders. Sampling can be performed also by inserting approximately 5-cc plastic boxes into oriented rock walls or by taking oriented blocks for subsequent sub-sampling. In the laboratory, samples are exposed to magnetic cleaning techniques that are able to define the magnetic component structure of the natural remanent magnetization (NRM). Cleaning is attained by exposing samples to either thermal or alternating magnetic field (AF) energy (Tauxe 2010). During thermal cleaning, samples are subjected to temperatures progressively increasing from room temperature to the Curie points of the constituent magnetic minerals, while during magnetic cleaning, to progressively increasing alternating fields up to the maximum coercivity of the magnetic minerals. The residual NRM is measured after each demagnetization step with a spinner or superconducting quantum interference device (SQUID) magnetometer, and the resultant variations in direction and intensity are visualized in so-called vector end-point demagnetization diagrams. Measurements are performed in a field-free space in order to limit the acquisition of spurious magnetic overprints. Magnetic component directions are extracted using least-square analysis on linear portions of the demagnetization diagrams. Standard Fisher statistics are used to calculate mean directions.

The most stable component of the NRM that can be isolated at high temperatures or AF fields is the characteristic remanent magnetization (ChRM), which is further investigated as a best candidate to represent the original (primary) magnetization acquired at the time of rock formation (as opposed to a secondary magnetization overprint, which is usually removed at lower temperatures or AF fields). This ChRM carries the magnetic polarity signal magnetostratigraphy is concerned with. Considering the northern hemisphere and excluding the effects of tectonic deformation or continental

drift, a ChRM directed to the north with positive (down-pointing) inclination is a record of normal polarity, while a ChRM directed to the south with negative (up-pointing) inclination is a record of reverse polarity.

Different rock magnetic experiments and reliability tests should accompany a magnetostratigraphic study. Experiments aim at determining the type of magnetic mineral(s) that carry the ChRM and their characteristics (grain size, domain state, etc.; Tauxe 2010). Reliability tests aim at constraining the age of acquisition of the ChRM. In a consistency test, the ChRM is considered primary when it defines a superposed sequence of magnetozones that can be laterally traced between distant sections and checked-upon by independent means (e.g., lithostratigraphy, biostratigraphy). A reversal test aims at determining the presence of residual and unresolved overprints by testing if the normal and reverse polarity component directions registered by the ChRM are antiparallel within statistical error (usually 95%). In a fold test, the ChRM directions from differently tilted beds of a cylindrical fold are compared on a stereographic projection before and after correction for the tilting of the strata: if after tilting correction they converge into a single distribution sharing the same mean direction, then this ChRM was acquired before tilting.

Timescales

Because magnetic polarity reversals occur aperiodically and are globally synchronous, they provide “bar code” patterns that can be used for correlations. When correlation is made to a geomagnetic polarity timescale, the numerical dating of a given rock sequence is also achieved. Various generations of timescales have been constructed over the years by integrating marine magnetic anomaly records with magnetostratigraphic, biostratigraphic, radiometric, and astrochronologic data from land sections and deep-sea cores (see Langereis et al. 2010). Classic timescales are those of Berggren et al. (1995) for the Cenozoic, and the astrochronological polarity timescale of Lourens et al. (2004) for the Neogene, while for

a recent summary of the Quaternary, see Ogg, Ogg, and Gradstein (2016).

In all these (and other) timescales, the youngest Chrons of predominant normal or reverse polarity straddling the last 6 Ma are named after leading geomagnetists: Brunhes, Matuyama, Gauss, and Gilbert (Figure 1). This sequence contains also magnetic polarity intervals of shorter duration called Subchrons, which are named after the locality where they were first observed (Jaramillo, Olduvai, etc.). A more formal classification also exists in which Chrons are prefixed by the letter “C” followed by a progressive number derived essentially from the correlative marine magnetic anomaly, complemented by the letter “n” or “r” indicating normal or reverse polarity; a final suffix may follow indicating Subchron subdivisions (Gee and Kent 2015). Examples are Brunhes Chron = C1n and Jaramillo Subchron = C1r.1n. The record of geomagnetic polarity reversal is known down to C34n (Cretaceous normal polarity Superchron, 83–120.6 Ma), then across the Jurassic and the Triassic, while for earlier times it is still largely incomplete (Ogg et al. 2016). There is also evidence of several magnetic polarity excursions of very short duration on the order of 3–6 kya (e.g., Mono Lake at 32 kya, Laschamp at 41 kya, Blake at 120 kya, Iceland Basin at 188 kya, Pringle Falls at 211 kya, Big Lost at 560–580 kya, Stage 17 at 690 kya, etc.; Laj and Channell 2015) that offer the potential of high resolution stratigraphy in the Quaternary, albeit their recording is frequently elusive in typically discontinuous continental records.

Key magnetic polarity reversal ages (Lourens et al. 2004) tied to Pliocene–Pleistocene stages (Ogg et al. 2016) that are relevant to archaeological studies (examples in Kukla and Nakagawa 1975; Parés and Perez-Gonzalez 1999; Laj et al. 2011) are shown in Figure 1 and are as follows:

- Base of Brunhes Chron (C1n) = 0.781 Ma (= Base of Middle Pleistocene).
- Top of Jaramillo Subchron (C1r.1n) = 0.988 Ma.
- Base of Jaramillo Subchron (C1r.1n) = 1.072 Ma.
- Top of Cobb Mountain Subchron (C1r.2r.1n) = 1.173 Ma.
- Base of Cobb Mountain Subchron (C1r.2r.1n) = 1.185 Ma.

- Top of Olduvai Subchron (C2n) = 1.778 Ma (~ Base of Calabrian).
- Base of Olduvai Subchron (C2n) = 1.945 Ma.
- Top of Reunion Subchron (C2r.1n) = 2.128 Ma.
- Base of Reunion Subchron (C2r.1n) = 2.148 Ma.
- Top of Gauss Chron (C2An) = 2.581 Ma (= Base of Quaternary/Pleistocene).

Alternative polarity reversal ages available in the literature may differ from those listed above by a few thousand years (e.g., ~0.773 Ma for the Base of the Brunhes; Channell et al. 2010; see also Singer 2014) depending on the dating method used.

Future directions

Among other topics, ongoing research is focused on (1) constraining the age of polarity reversals to within one precessional cycle, (2) confirming polarity excursions from multiple records, (3) integrating magnetostratigraphy with paleointensity data, and (4) retrieving magnetostratigraphic signals from samples with resistant overprints.

Obsidian Hydration Dating

LAWRENCE M. ANOVITZ

Oak Ridge National Laboratory, USA

MOSTAFA FAYEK

University of Manitoba, Canada

Introduction and history

Obsidian hydration dating (OHD) is based on the fact that artifact manufacture exposes fresh, unweathered surfaces to the environment. Water from that environment then enters the glass by diffusion at a rate set by various factors, including the composition of the glass, the external temperature, and the relative humidity. If the appropriate diffusion coefficients are known, the depth of the diffusion can be correlated to the time over which the process occurred, that is, to the age of the artifact.

Archaeological interest in obsidian hydration began with the work of Friedman and Smith (1960). Friedman and co-workers concluded that the position of the hydration front could be fit to a quadratic equation with time, and modeled on Fick's Laws as:

$$x^2 = Dt \quad (1)$$

where x is the thickness of the hydration rim, D is the hydration rate, and t is time. Because the hydration rate is temperature dependent equation, (1) was combined with the Arrhenius equation, yielding:

$$x^2 = Ate^{-E/RT} \quad (2)$$

where A is a constant, E is the activation energy, R is the gas constant, and T is absolute temperature. Equation (1) is, however, a "rule of thumb" for diffusion modeling, not a solution to Fick's Laws, as it does not describe changes in water concentration with distance and time.

Unfortunately (see Anovitz et al. 1999), application of this work to archaeochronometry

has been plagued by both imprecision and inaccuracy. Anovitz et al. (1999) provided an example from the Chalco site in the Valley of Mexico that showed not only poor correlations with associated ^{14}C ages, but also significantly poor precision and accuracy. They showed this was, in part, due to the optical method used for analyzing the hydration depth in nearly all studies, and that the hydration profile (concentration with depth) observable using secondary ion mass spectrometry (SIMS) did not follow a simple error-function-like pattern, but was S-shaped, suggestive of a concentration-dependent diffusion mechanism. Experimental study of diffusion in Pachuca obsidian by Anovitz et al. (2004; 2006a) further showed that, even when reliable data were obtained, the penetration rate did not, necessarily, proceed as the square root of time.

Deviations from error-function solutions to Fick's Law are a function of the degree of structural change produced by the migrating species. As water is a network modifier in glass, and lowers its viscosity, the diffusion coefficient of water in glass should increase with increasing water concentration. Friedman et al. (1966) suggested that water concentration profiles in hydrated obsidian should be square or S-shaped.

The possibility of surface dissolution was also recognized as a potential problem for OHD. Friedman and Smith (1960) felt that it would be a problem only in rare instances. Efforts to correct for surface dissolution in archaeological samples have been limited to measuring hydration rinds in fissures located along the surfaces of artifacts.

In a series of papers using SIMS to measure hydration profiles, Anovitz and co-workers criticized standard approaches to OHD, suggested an alternative, and studied the rates and mechanisms of the hydration process. Anovitz et al. (1999) noted the consistent failure of traditional OHD to yield reliable results and attributed this to both the analytical methods employed and the mathematical description of the process. They also suggested that SIMS could be used to directly measure water concentration as a function of depth, provided examples for several

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0416

types of glasses, and showed that reasonable fits to the hydration profiles could be obtained, except in the very near-surface region, using a compositionally dependent diffusion model. Riciputi et al. (2002) tested this approach using samples of Pachuca obsidian from the Chalco site in the Valley of Mexico for which good stratigraphically correlated ^{14}C dates were available. They developed a “characteristic point” approach whereby the complex diffusion profile could be characterized by a single depth, and showed that neither the traditional OHD equation for depth as a function of the square root of time nor a linear function fit the data. Rather, an excellent fit was obtained for a more generalized value ($\sim t^{0.75}$). They also showed that, using only two obsidian samples and their associated ^{14}C dates, a calibration curve could be derived that provides dates for other samples in excellent agreement with their associated ^{14}C dates. Finite difference modeling was also used to reproduce the shape of the hydrogen depth profile assuming concentration-dependent diffusion, and the dates obtained agreed well with associated ^{14}C ages. These results clearly indicated that, when empirically calibrated, hydration dating is feasible using SIMS, an approach they labeled ODDSIMS. Anovitz et al. (2004) presented experimental data on the hydration of Pachuca obsidian at 75°C for times ranging from 3 to 562 days, and compared these results with those from Chalco. They developed a technique for these experiments in which the samples were exposed to water vapor, rather than liquid water, with a chemical potential equal to that of the liquid at the pressure and temperature of the experiment, in order to reduce or eliminate uncertainties due to dissolution. Again, the results demonstrated that a simple square-root-of-time model was not adequate.

A key component of the work of Riciputi et al. (2002) was that the samples were locally calibrated, eliminating the effects of unknown local temperature patterns through time. Anovitz et al. (2006a) inverted this approach, combining an experimental calibration of the hydration rate of Pachuca obsidian as a function of temperature with the known ages of the samples to calculate integrated paleotemperatures as a function of time. Anovitz et al. (2006a) evaluated the effects of relative humidity on hydration rates and found that for relative humidity levels commonly

observed in most soils the effects on hydration dating should be relatively small.

Anovitz, Cole, and Fayek (2008) investigated the mechanisms of obsidian hydration. Comparisons between high- and low-temperature diffusion suggested that water concentrations in rhyolitic glasses hydrated at low temperatures are significantly greater than in those hydrated at high temperatures and low pressures. Surface concentrations, which equilibrate quickly with the surrounding environment at high temperature, change more slowly as temperature decreases, and may not equilibrate at room temperature for hundreds or thousands of years. A change in mechanism may be due to the inability of “self-stress,” caused by the in-diffusing species, to relax at lower temperature. These stresses may be greater than the tensile strength of the glass, and Fourier transform infrared spectroscopy (FTIR) analysis suggested the in-diffusing species was primarily molecular water. Anovitz, Cole, and Riciputi (2009) further investigated these processes by varying the isotopic composition of the in-diffusing water to determine whether a point-by-point analysis of the D/H or $^{18}\text{O}/^{16}\text{O}$ isotopic composition across the hydrated rim can be used as a paleoclimatic monitor. They found that both the isotopic composition of the waters of hydration, as well as that of intrinsic water from the initial glass formation vary dramatically during hydration, and a point-by-point paleoclimatic reconstruction is not feasible. However, once the glass is fully hydrated, and chemically driven diffusion is no longer occurring, isotopic reconstructions may be possible.

Techniques

Friedman and Smith (1960) noted that the hydration rim was visible under high-power magnification, and suggested that its width was dependent on time, chemical composition (obsidian source), and temperature. Based on their observations, three techniques utilize this concept to date obsidian.

Optical methods

Initial OHD work involved two optical methods. The empirical rate method correlates rim

widths with independent chronometric data (e.g., radiocarbon). The intrinsic dating method ratios rim widths to laboratory-determined hydration rates. The latter directly dates obsidian artifacts, is simple, rapid, and inexpensive (it uses an optical microscope), and allows a large number of chronometric determinations to be obtained from a single site. Unfortunately, consistently reliable results have not been achieved using this method because of two factors: (1) the inherent imprecision in any measurement done using visible light (i.e., errors inherent in optical measurement of hydration rim thickness), and (2) the formation of the Becke line (a bright line that occurs in thin sections at the boundary between two materials with different refractive indices, whose position is focus-dependent (Anovitz et al. 1999). In addition, the rim is clearly gradational (Figure 1).

Secondary ion mass spectrometry (SIMS)

As a consequence of the inaccuracy associated with optical OHD, Anovitz et al. (1999) developed a new approach using SIMS. They showed that the shape of the water profile is inconsistent with that predicted using current OHD equations, indicating that the theoretical basis for OHD is flawed.

SIMS is an excellent method for obtaining high-precision information on the concentration of water as a function of depth, and therefore is an ideal technique to investigate the process of obsidian hydration. When utilized in depth-profiling mode, SIMS can resolve concentration variations over a few nanometers for a wide variety of elements, over depths ranging from tens of nanometers to several microns. SIMS is based on analysis of ions ejected from a sample during bombardment by a focused beam of primary ions accelerated at 2–20 keV. The composition of these secondary ions is representative of the composition of the sputtered surface, so a mass spectrometric analysis provides a quantitative elemental or isotopic analysis of the sputtered volume. Depth resolution is typically in the 0.02–0.04 μm range, although the instrument can be adjusted to obtain much finer resolution (Anovitz et al.

Figure 1 Typical hydration rim on a 180,000-year-old obsidian tool from Gademotta Ridge, Ethiopia. Presence of a significant stress field is apparent in thin sections of hydrated obsidian, as hydrated regions are optically anisotropic. Crossed polars, 1 λ accessory plate, figure width = 0.125 mm.

1999). Although this ODDSIMS technique provides several advantages over the optical method (e.g., shape of hydrogen profile, accurate and precise results independent of the analyst), there are several disadvantages. These include (1) cost of analysis; (2) diffusion rates are compositionally dependent and, therefore, diffusion experiments on obsidians with compositions similar to the artifacts are required to develop calibration curves. This is time consuming and expensive; and (3) local calibration curves, similar to those developed by Riciputi et al. (2002),

require samples with well-defined ^{14}C ages. This renders ODDSIMS an empirical rate dating method, rather than a stand-alone intrinsic dating method.

Liritzis (2006) published a SIMS study of obsidian from several sites in Greece, the United States, and Mexico, where he took into consideration the surface saturation (SS) layer and dubbed his method SIMS-SS. This is based on Fick's Law, and relates concentration to hydration depth. It incorporates the surface saturation layer and equations that describe the diffusion rate. The diffusion coefficient is assumed to vary exponentially and is derived from the first derivative of the diffusion profile. Liritzis (2006) argues that the SS layer forms relatively quickly and there is no true time-dependence of the surface concentration, which contradicts the results of Anovitz et al. (2004) which show increasing near-surface concentration of hydrogen with time. SIMS-SS results are not, however, based on controlled, experimentally derived data, but on archaeological artifacts, and do not take into consideration the chemical composition of the material examined.

Infrared spectroscopy

Stevenson and Novak (2011) used infrared transmission spectroscopy to study molecular water diffusion in experimental obsidian samples at low temperatures (90–190 °C). The obsidian samples varied significantly in the concentration of structural water within the unhydrated material. Long-term (60–360 days) hydration sequences at 90 °C showed a $t^{0.6}$ time dependence for the uptake of molecular water forming the hydration layer. The structural water concentration of the unhydrated bulk obsidian is highly correlated with the pre-exponential coefficient and activation energy and may be used to estimate Arrhenius constants to determine obsidian hydration rates at ambient temperature (i.e., develop calibration curves for archaeological artifacts). The advantage of this approach is its ability to estimate rates of water diffusion based upon glass composition. In addition, it can estimate rates of diffusion for individual artifacts rather than using a generalized composition for geological sources or flows from

which the artifact originated. The disadvantage is that it is destructive. Development of calibration curves requires preparation of polished slabs cut from the artifact. Similarly, hydration rim measurements require that the hydrated surface is separated from the rest of the sample. Sample preparation techniques are very exacting and can destroy the entire sample, limiting the number of samples dated.

To avoid some of these issues, Stevenson, Lade-foged, and Novak (2013) investigated infrared photoacoustic detection. This method measures water in solids based upon the thermal response to infrared heating. Although it is also destructive, it requires less tedious sample preparation and has the ability of analyzing opaque obsidians. They applied this method to artifacts recovered from Rapa Nui (Easter Island), and were able to correlate the ages they obtained using infrared photoacoustic detection with ages obtained using accelerator mass spectrometry (AMS).

Future prospects

In their initial paper on the subject, Anovitz et al. (1999) labeled OHD, as it was then known, a failure. The demonstrated poor precision and/or accuracy of optical techniques continue to justify the original conclusion. However, available evidence suggests that, in modified form, obsidian hydration dating may remain useful. At least two criteria must be met. First, accurate measurements of the extent of hydration must be obtained. SIMS provides such an analytical approach. While, in our estimation, a definitive demonstration is not yet available for the FTIR technique, this approach of Stevenson has significant promise.

The second limitation is calibration. Even where experiments (e.g., Anovitz et al. 2006a) provide a careful, polythermal, calibration of hydration rates, significant difficulties must be addressed. First, such calibrations are extremely time consuming, and thus unlikely to be available for many sources. Second, because diffusion of water into obsidian is temperature dependent, calculations based on an externally calibrated hydration rate depend on determination of hydration temperature. This value cannot be known, a

priori, unless local variations in paleoclimate are known over the entire burial history of the artifact in question. Thus, the best solution is likely to use OHD as a secondary technique, calibrating local rates relative to other approaches such as ^{14}C . As a final caveat, however, it is by no means certain that obsidians from all flows, or even parts of a given flow, from a given source hydrate at the same rate, and thus the utility of this modified approach remains to be further tested.

We have arrived at these conclusions thanks to the support of the United States Department of Energy, Office of Science, Office of Basic Energy Sciences, Chemical Sciences, Geosciences, and Biosciences Division, and the NSERC Discovery Grant.

Quaternary Large-Mammal Zones

JAN VAN DER MADE

Consejo Superior de Investigaciones Científicas,
Museo Nacional de Ciencias Naturales, Spain

Background

A rock unit, characterized by the occurrence of fossils of a particular species or a combination of species, is called a biozone and the time in which these organisms lived is called a biochron. A sequence of biozones is called a biozonation and gives the “relative” ages of the biozones to each other (“older/younger than,” etc.). Biozones may be based on many kinds of organisms, including large and small mammals. The Quaternary corresponds to the past 2.6 million years of the Earth’s history. This is close to the maximum age of the archaeological objects that are known. The branch of science that uses biozones to study the relative ages of strata is called biostratigraphy and has been the main method to compare ages in geological and archaeological contexts, and it still is, when physical methods cannot be applied. If such methods, like uranium series and electron spin resonance dating, or paleomagnetism have been used to date the biozones, we know their “absolute” age, expressed in thousands or millions of years (kya or Ma, respectively).

Historical development

The notion that there had been different periods with different species of animals became widespread in the eighteenth century. Around the turn of the century, it was known that different geological formations were characterized by different fossil contents, representing different periods, and this information was used to produce geological maps by William Smith in Britain and Georges Cuvier and Alexandre Brongniart in France. This is the beginning of biostratigraphy.

By this time, it was known that species could go extinct and to some extent that new ones might originate: Lamarck and Darwin published their theories on evolution in 1809 and 1859, respectively.

In the middle of the nineteenth century, d’Orbigny and Oppel were among the first to use the term “zone,” either for a rock unit or time unit, characterized by fossils of certain organisms. Zones are the smallest stratigraphic units. The first edition of the *International Stratigraphic Guide* (Hedberg 1976) considered a zone to be a body of strata with a particular content, limited by diachronous borders, while the corresponding chronozone is the total time range of this content. This content can be fossils (biozone), lithology (lithozones), minerals, and so on. The fossil content that defines a biozone can be the total range of a taxon (species, genus, etc.), the coincidence of two or more taxa, the presence of one taxon and the absence of another, the particular abundance of a taxon, and so on. A biozone is usually named after the defining taxon or taxa, but if the zone is part of a sequence, it is often numbered. A taxon may appear suddenly or it may gradually spread into a geographic area. If such a taxon is used to define the boundaries of a biozone, the boundary will be synchronous in the first case and in the second it will be diachronous. The corresponding chronozone or biochron covers the total time range from the first till the last appearance.

Practical constraints to large mammal zones

Biozonations are affected by the different sedimentary environments with different potentials for the preservation of fossils. In the deeper parts of the seas, thin clay layers may incorporate abundant microfossils, allowing for a precise study of biological change. By contrast, on the continents, erosion prevails and sedimentation is patchier, both in time and space. As a result, continental long continuous sedimentary sequences are much less common than marine

DOI: 10.1002/9781119188230.saseas0486

ones. Continental biozonations are often based on pollen or the remains of mammals. Fluvio-lacustrine environments and caves tend to have the best fossilization potential for mammals, but are prone to have hiatuses. Microfossils may be evenly distributed in fine sediments, while concentrations of mammal fossils are usually hard to find, especially of large mammals. While soaking and sieving a small piece of marine clay may rapidly yield a nice collection of foraminifera, collecting small mammals is more time consuming and the excavation of a large mammal locality often takes several years and is usually done by a team. These practical differences lead to differences in biostratigraphical procedures and even to separate large and small mammal biozonations, even though there are many localities where both occur together. There has been much discussion on the methodology to be followed in mammalian biostratigraphy, whether type sections should be used, whether the best faunal criterion for boundaries was dispersal events or evolutionary “steps,” and so on.

In Europe, there tends to be much vegetation, the geological strata cannot be easily seen as in arid landscapes, and there is a long tradition to excavate known fossil localities. As a result, the ages of these localities (or their fossil associations) are compared, rather than the ages of geological strata. This custom developed into biostratigraphic schemes in which reference localities (often from quite different areas) are placed in a supposed chronological order. Nearly none of the presently used mammal biozonations for the European Quaternary, Neogene, or Paleogene follows strictly the International Stratigraphic Guide, and many stratigraphers do not even consider them to be biozones, but call them simply “units.”

Biozonations based on large mammals are attractive for the study of prehistory, since one of the indications of human activity is bone accumulations due to hunting. Large mammal zonations have been proposed for most continents, but in some, human presence (and thus archaeology) is well within the range of C^{14} dating and younger than most or all recognized biozones. The latter is the case in Australia and the Americas. In Asia, where there is either insufficient detail or no biozones have been formally defined that cover human presence.

Relevant large mammal biozonations

Azzaroli (1967) divided the Villafranchian into what he called the lower, middle, and upper zones, which corresponded to sub-stages of previous authors. Later he recognized five “faunal zones” or units. This developed into a scheme with 13 faunal units covering the Quaternary (Gliozzi et al. 1997) (Figure 1). No boundaries were defined, but the scheme is accompanied by a range chart, where the entries and exits of the taxa are indicated. Each unit is called after a reference locality, nearly all of them Italian. Notwithstanding, the scheme is used also outside Italy.

Guérin (1982) defined the MNQ (Mammal Neogene Quaternary) units as an extension of the previously existing MN units for the European and circum-Mediterranean Neogene and continued the numbering. There have been several updates (e.g., Faure and Guérin 1992). Twelve units, MNQ 16–27, correspond to the Quaternary. Each of these units is defined with a variety of criteria: characteristic stages of several evolutionary lineages, several “typical” associations of two taxa, several first appearances. Most importance is given to rhinoceroses and other large mammals, but also small mammals are used.

The MmQ biozones were defined on the basis of small mammals, but include as additional information many large mammals (Agustí, Moyà-Solà, and Pons-Moyà 1987), and have been used by others working on large mammals.

Coppens (1972) introduced a biozonation or biostratigraphic scheme for Africa, of which zones I–IV correspond to the Quaternary. Based on the evolutionary stages of lineages in the Suidae and Elephantidae, Maglio (1972) recognized three biozones, which were modified by Harris (1983). These are true biozones, based on rock sequences with their fossil contents. They cover the period between some 3 and 1 Ma.

The future of biozonations

Many of the East African deposits are well dated because of the widespread tuffs, so that the ages tend to be given directly and the use of biozones is now largely abandoned. In Europe, it does

Figure 1 The main large mammal zones of the Quaternary of Europe and Africa. Ages are approximate and the position relative to oxygen isotope stages follows Gliozzi et al. (1997).

not seem likely that in the near future, physical methods of dating will replace biostratigraphy. However, all of the biozones or units were defined a long time ago. Research on the evolution of the large mammals has proceeded and present taxonomy is often not in accordance with the information on which the biozones were based. In any case, by now more precision is wanted. The average duration of the Italian faunal units, the MNQ, and MmQ zones is around 200, 217, and 325 kya, respectively. However, for the European Middle Pleistocene one would like enough

precision to recognize the major climatic cycles (with an average duration of about 100 kya) and correlate to the marine oxygen isotope stages. Another problem is the accuracy of the biozonations. Either no specific boundary criteria were given, or several, which, occasionally, with the present state of knowledge, correspond to different climatic cycles or to the warm and cold phases of a single cycle.

For biostratigraphy to continue to be a useful tool in prehistory and geology, more precise biozones should be defined. Middle and Late

Pleistocene zones should aim to recognize at least the glacial and interglacial phases of each major climatic cycle, which means an average duration of about 50 kya. It might prove to be difficult to recognize each of the glacial phases, since their faunas tend to be less known, but such a precision should be possible for the interglacial phases. Each boundary should be precisely defined by a single criterion, while additional criteria should be used, recognizing their lesser value in case of conflict. The validity of the definitions of the units should be regularly evaluated and compared to other information on the ages of the localities.

Quaternary Micro-Mammal Zones

GLORIA CUENCA-BESCÓS

Aragosaurus-IUCA—University of Zaragoza, Spain

Introduction

The archaeological and paleontological histories during the Quaternary need a fine, accurate, and global time framework, that is, a Quaternary timescale. A time-based framework allows us to view the entire system, including sites, taphonomy, paleoecology, sequences, and cultural and biological (paleontological) evolution, rather than considering only individual circumstances. Relative dating using the fossil content follows the geological principle of faunal succession of William Smith (England, 1700s), who noticed that the species—namely “*kinds of fossils*” in the 1700s—change through a vertical succession of strata, and also that the same vertical changes in fossils occurred in different places. Using the fossils collected from rocks in one part, it is possible to predict the succession of rocks and fossils in other parts. This is known as the biostratigraphic correlation. The use of fossils to determine the age of rocks is based on the fact that organisms change permanently in a progressive and irreversible evolutionary process. For this reason, geologic time can be divided into successive intervals, or zones, characterized by associations of fossils in each zone. There are different ways of subdividing the strata in biostratigraphic zones; that is, there are different types of biozones. They may be defined on the basis of a single taxon or associations of taxa, relative abundances of taxa, or variations in features related to the distribution of fossils (see “Taxonomy” below). The usual limits of a biozone are based on the first and/or last appearance datum/occurrence of taxa (FAD, LAD). The biozones are made conventionally after studying different stratigraphic sections. The rules, nature, and more details about the biostratigraphic units

can be read in the Stratigraphic Guide of the International Commission on Stratigraphy.

Biozonation based on micromammals

Biozonation based on macromammalian assemblages has long served as a biostratigraphic framework in several places (see QUATERNARY LARGE-MAMMAL ZONES). Biostratigraphy is also acquiring high precision when used with micromammals in archaeological and/or paleontological sites (Cuenca-Bescós et al. 2010, 2016a, 2016b; Maul and Markova, 2007; Repenning 2003; Kawamura and Zhang 2009). Relative dating and constructing time in archaeology is based mostly on micromammalian zones because ideal taxa for biozones are those with abundant fossils, which show good preservation of the diagnostic characters in the fossil record, and rapid evolution of their species. These three conditions are achieved with micromammals. During the Quaternary, the abundance and rapid evolution of certain lineages of lagomorphs, rodents, and insectivores make these groups the best tools for biostratigraphy and biochronology. Recent quantitative methods applied to biochronological correlation with small mammals have improved the resolution of the biochronological time framework (Cuenca-Bescós et al. 2016a, 2016b; Galster, Guex, and Hammer 2010). The reason is that their teeth are accumulated in great numbers in archaeological sites. The isolated teeth are composed of very hard skeletal tissues and are diagnostic in their taxonomic classification. Moreover, paleontological studies of rodents show that they are mammals with fast evolutionary rates (Bininda-Emonds 2007). A good example is the evolution of the faunal succession during the Early Pleistocene in the archaeological and paleontological sites from the Trincheras del Ferrocarril in Atapuerca: In nearly half a million years the micromammals’ associations change completely; during this interval, there is the LAD of 12 species and the FAD of 13 (Cuenca-Bescós et al. 2010, Figures 4 and 5).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0487

Archaeological site and digging of micromammals

Microvertebrates in general are not encountered through standard excavating methods, and specialized recovery techniques are generally required to obtain such taxa. Techniques include washing and sieving sediments, and once the sediments have been washed off, we obtain fine and coarse concentrates. These are spread thinly and evenly in a sorting tray that is marked with a grid system, and then fossils are removed with fine forceps and the naked eye or optical devices (Cifelli, Madsen, and Larson 1996).

Taxonomy

In taxonomy, the taxon (plural taxa) is the systematic categorization of any fossil or living organism, such as phylum, order, family, genus, or species, though the basic unit for biozonation

is the species. Classification of the species is based on the identification of the diagnostic characters in the fossil teeth, usually the first lower molar in several groups of rodents, and the mandible and postcranial elements in insectivores and bats (Cuenca-Bescós et al. 2010, 2016a).

Micromammalian zones during the Pleistocene

The Pleistocene is a time span that represents important faunal turnovers. Evolution of faunas and biostratigraphy of the continental Pleistocene have in general faced the problem of being based on isolated sites and on short and mostly discontinuous sequences. The search for good and complete stratigraphic sequences to analyze micromammalian changes through the vertical succession of strata have been the main concern of paleontologists all over the world.

Figure 2 Biochronology and biozone boundaries of the Quaternary in Europe based on FAD and LAD of small mammal species.

Western Europe

In western Europe, there are the sequences of Kozarnika Cave (Bulgaria), Kärlich (Germany), and Zújar and Atapuerca (Spain). The continuous archaeological and paleontological record in the Sierra de Atapuerca caves, which contain the most extraordinary accumulation of evidence of human evolution in Europe, ranging nearly continuously from the Early Pleistocene to the Late Pleistocene and Holocene, and with its abundant micromammalian fossil record, offers the possibility of recognizing faunal replacements, dating their numerical age, establishing a stratigraphic range of faunal associations, and correlating them with reference localities in Europe (Cuenca-Bescós et al. 2010, 2016a, 2016b).

The evolution of several lineages of micromammals and the succession of faunal events, such as the FAD and LAD pertaining to important fossil markers, which can be calibrated with magnetostratigraphic and radiometric data, permit the definition of biozones (or faunal units

(FU)). An update of the European microfauna has been published in a volume devoted to the biochronology, biostratigraphy, and paleoecology of small vertebrates from archaeological and paleontological sites in Cuenca-Bescós et al. (2016b). The biostratigraphy of the Quaternary of Europe based on small mammals has a long tradition, with the works of Major, Hinton, and Cuvier, and during the twentieth century when several authors contributed to the European biozonation, such as Agustí, Chaline, Kotsakis, Markova, Mein, van der Meulen, Nadachowski, Heinrich, Kowalski, Fejfar, Sala, and Tesakov—a foundation that we can only improve by going through the taxonomy and paleobiology of small mammals using new techniques such as scanning electron microscopy, computed tomography, biomechanical, biomineral, histological, and ultrastructural studies, and by using statistical methods. A proposed biostratigraphic correlation for the Quaternary sites of Spain with micromammals is shown in Figure 1.

Central and eastern Europe

Among rodents, arvicolines are the best micromammalian tools for biostratigraphy (Fejfar, Heinrich, and Kordos 2011). Maul and Markova (2007) provide an interesting and critical overview of the biozonation in central and eastern Europe based on these rodents. As in the example provided for western Europe, the authors suggest a good number of stratigraphic sections and localities and provide a chart of the micromammalian zones in central and eastern Europe (Figure 2).

Asia

Biostratigraphic correlation between Europe and Asia has been made almost exclusively using micromammals, especially rodents, which show rapid dispersals from northern Asia to China. Studies of fossil ochotonids and arvicolines related to archaeological and paleontological sites are gaining relevance, especially after new discoveries of archaeological localities in the Baikal region in Russia and in China (Erbajeva and Alexeeva 2013; Kawamura and Zhang 2009).

North America

As in Asia, the primary biochronologic controls are the brief periods of rapidly spreading or dispersal events of rodent faunas (mainly arvicoline, or microtine for American authors). Repenning shows that the micromammalian zones build with arvicoline rodents to provide a nearly complete correlation of Pleistocene events throughout most of Holarctica, from the Early Pleistocene to the oldest of 14C dates. The dispersal events apparently occurred near the ends of episodes of most extensive grasslands (Repenning 2003).

Radiation Exposure and Dating

DIDIER L. BOURLÈS

Aix-Marseille University, France

The cosmogenic nuclides

Cosmic-ray particles impinge continuously and isotropically (invariant with respect to direction) onto the Earth's atmosphere, in which they dissipate their energy efficiently through nuclear reactions, leaving cosmogenic nuclides as residues. The flux and energy of the primary and secondary particles (primarily neutrons) produced in the nuclear cascades thus exponentially decrease as a function of the thickness of atmosphere crossed, and only about 0.1% of them reach sea-level with enough energy to induce nuclear reactions in the Earth's crust (in-situ production). While in the atmosphere the production rate of cosmogenic nuclides exponentially increases with altitude, in the Earth's crust, it exponentially decreases with depth. Currently, the cosmogenic nuclides most used in archaeological sciences are ^{10}Be , ^{26}Al , and ^{36}Cl .

The accelerator mass spectrometry (AMS)

The mode of production of the cosmogenic nuclides implies they are rare in natural environments. Comparatively, isotopes (same atomic number but different mass number) and isobars (same mass number but different atomic number) of these cosmogenic nuclides are overwhelmingly abundant. Thus, the concentration of the stable ^9Be isotope and of the isobaric boron (^{10}B) is at least 10^8 times higher than that of ^{10}Be , which prohibits the use of the mass spectrometry technique whose level of separation cannot exceed 10^5 – 10^6 . It is the same for ^{26}Al , whose atmospheric production rate is 250 times lower than

that of ^{10}Be and whose stable isotope, ^{27}Al , is naturally abundant ($^{26}\text{Al}/^{27}\text{Al} \sim 10^{-14}$ – 10^{-15}). For ^{36}Cl , the abundance ratios $^{36}\text{Cl}/\text{Cl}$ are between 10^{-12} and 2×10^{-14} . Counting radioactive decay also poses serious technical problems. The ^{10}Be production rate in the atmosphere being about 100 times smaller and its half-life 300 times longer than that of ^{14}C , the activity of ^{10}Be is about 3×10^4 lower than that of ^{14}C , with that of ^{26}Al and ^{36}Cl being, respectively, about 3×10^6 and 3×10^5 times lower.

The necessity of fully exploiting the potential of the cosmogenic nuclides ^{10}Be , ^{26}Al and ^{36}Cl , by lowering the detection limit to a few hundred thousand atoms, led to the development of the AMS technique. To unambiguously identify, detect, and finally count the number of atoms of interest, we must have access to both to the mass number and the atomic number. For a given energy, the mass number corresponds to a specific radius of curvature in a given magnetic field (Lorentz force). Also the atomic number corresponds to a specific energy loss in a given material thickness (Bethe-Bloch law). The use of the unique characteristic of the energy loss in a thin material thickness followed by the detection/characterization in a suitable detector is possible only if the atom of interest has an energy high enough to allow both steps to be performed sequentially. Therefore, very schematically, the AMS technique inserts an acceleration stage between the injection and the analysis section of a conventional mass spectrometer.

Atmospherically produced cosmogenic nuclides

Given its production from the two most abundant constituents of the atmosphere (nitrogen and oxygen), and its long half-life (1.387 ± 0.012 million years (Ma)) allowing dating over ~ 10 Ma, ^{10}Be appears as a powerful dating tool.

Once produced in the atmosphere, ^{10}Be is oxidized. Then it attaches to aerosols and is introduced into the environment in a soluble form

DOI: 10.1002/9781119188230.saseas0490

through wet and dry precipitation. Finally, it is either adsorbed on settling particles (scavenged) and deposited in marine or lake sediments, or effectively retained on the surface of continental sediments. Immobilized and isolated from the exchange cycles, this cosmogenic radionuclide then decreases according to its own half-life and thereby becomes a potential tool for dating reservoirs where it has accumulated.

However, the absolute ^{10}Be concentration depends on variations in environmental parameters such as sedimentation rate, mineralogical composition, grain size, and so on. Its use as a dating tool requires overcoming the temporal changes in these parameters by normalizing the ^{10}Be concentration to that of the stable ^9Be isotope, which has a strictly identical chemical behavior.

Present in the minerals constituting terrestrial rocks, stable ^9Be is brought to oceans and lakes from rivers, winds, and hydrothermal fluids after weathering and erosion of these rocks. Although most of it stays in the sedimentary particles, a proportion is dissolved and remains in a soluble form in the acidic medium of watercourses, and finally rapidly adsorbs onto the particles that settle in the more alkaline ocean or lake environments.

Given their different pathways in the terrestrial environment, only the soluble form of both beryllium isotopes can be homogenized before adsorption onto the particles and sediment deposition. Adsorbed on the surface of the particles with a ratio representative of the water mass that contained them, the ^9Be and ^{10}Be isotopes participate in the formation of the authigenic phase (the phase formed from dissolved elements) of the sediments. Only this authigenic phase should be considered for dating.

The authigenic $^{10}\text{Be}/^9\text{Be}$ concentration ratio will therefore have to be determined in the authigenic phase extracted using a specifically developed leaching method. The latter was validated by studies demonstrating that the ratios measured in the authigenic phase leached from sediments at the interface with seawater were equal to those measured in the dissolved phase of the overlying seawaters. The dates are then obtained using the classical equation of radioactive decay: $N_t = N_0 \cdot e^{-\lambda t}$ (where N_t is the

measured authigenic ratio; N_0 the initial authigenic ratio; λ or $\ln 2/T_{1/2}$ the radioactive decay constant; and t the age of the sediment).

Like any radiochronological dating method, the dating method based on measuring the authigenic $^{10}\text{Be}/^9\text{Be}$ ratio from sedimentary deposits is applicable only if the sediments remained as a closed system (free of losses and/or gains with the external environment) since their deposit, and if it is possible to constrain the initial authigenic $^{10}\text{Be}/^9\text{Be}$ ratio (N_0), namely, the value of the initial stock when the losses due to the sole radioactive decay initiate.

This dating method, theoretically applicable for a period of time ranging from 0.2–10 Ma, has been successfully applied to the dating of sedimentary units in the Chad Basin (Lebatard et al. 2010).

In-situ produced cosmogenic nuclides

Application to dating of the in-situ produced cosmogenic nuclides is based on the fact that their production is limited to the first few meters below the Earth's surface. Indeed, the cosmic ray particles rapidly dissipate their energy during their nuclear interactions with the surface rocks because of the density of the latter, which implies that the intensity of the cosmic rays and therefore the in-situ production of cosmogenic nuclides decreases exponentially with the rock depth. The dating method does not therefore rely on the radioactive decay of an initial stock, as previously discussed, but on measuring the concentration of newly produced cosmogenic nuclides having been accumulated in the selected mineral after a geological process has brought it close to the surface. The event dated is therefore the event causing the exposure to cosmic radiation. It must, however, be assumed that the dated substrate was buried deep enough to be protected from the effects of cosmic radiation before being brought to the surface.

Assuming that the gains in in-situ produced cosmogenic nuclides are due solely to cosmic-ray induced nuclear interactions in the sampled material, while the losses result from both

radioactive decay and denudation, the cosmogenic nuclides thus accumulate in the rocks until their concentration reaches a steady state corresponding to a state where production induced by nuclear reactions equals losses by radioactive decay and denudation. The more active are the denudation processes, the more rapidly is this steady state reached (Gosse and Phillips 2001).

Following geomorphological and geological studies demonstrating the blocking of the Chauvet cave paleoentrance by rockfall deposits, the cosmic-ray exposure (CRE) dating method has been applied to the Chauvet cave. The in-situ produced ^{36}Cl concentration measurements performed on surface samples from the three concave rockslide scars located on the 47-m high cliff overhanging the cave paleo-entrance date the first rockfall event back to 29,000 years ago, and the most recent one that permanently blocked the paleoentrance to at least 21,500 years ago. These ^{36}Cl dates confirm the accuracy of the radiocarbon ages (Sadier et al. 2012).

Burial dating

Environmental changes or human activities can induce burial of surface samples previously lying on areas affected by denudation. Then, below a depth limit, the only process operating is radioactive decay of the isotope in question. In this case, for any surface being eroded, the significantly different ^{10}Be and ^{26}Al radioactive decay constants imply that the $^{26}\text{Al}/^{10}\text{Be} = f([^{10}\text{Be}])$ curve evolves between two limit curves defining an area called the “island of the stationary states” (Figure 1). The upper envelope of this surface corresponds to the set of solutions for finite exposure duration at a zero denudation rate, while the lower envelope corresponds to the set of solutions for different denudation rates at infinite exposure duration. These two curves define three zones in the $^{26}\text{Al}/^{10}\text{Be} = f([^{10}\text{Be}])$ diagram. The “forbidden zone” is the area to the right and above the upper envelope curve. Any point in this zone cannot be explained by a geomorphological model and therefore most probably results from an analytical error. The

Figure 1 $^{26}\text{Al}/^{10}\text{Be} = f([^{10}\text{Be}])$. The upper curved lines delimit the “island of the stationary states” zone. The parallel curved lines below denote both the ^{10}Be concentrations and the $^{26}\text{Al}/^{10}\text{Be}$ ratios reached after their corresponding burial duration for denudation rates ranging from 0 to a few 10 cm/ka. The straight diagonal lines exhibit the evolution of both the ^{10}Be concentration and the $^{26}\text{Al}/^{10}\text{Be}$ ratio due to radioactive decay for various samples buried from surfaces experiencing the indicated denudation rate.

zone between the two limit curves corresponds to all possible ^{10}Be concentrations and $^{26}\text{Al}/^{10}\text{Be}$ ratios for surfaces undergoing denudation. The zone to the bottom left of the “island of the stationary states” corresponds to all possible ^{10}Be concentrations and $^{26}\text{Al}/^{10}\text{Be}$ ratios for surfaces undergoing or having undergone burial. Indeed, when a previously exposed surface is finally buried enough to be protected from cosmic rays, then losses due to radioactive decay alone imply a decrease in concentrations of the cosmogenic nuclides. These decreases, depending on the half-lives of the considered nuclides, imply for the $^{26}\text{Al}/^{10}\text{Be} = f([^{10}\text{Be}])$ diagram an evolution such that any point initially corresponding to a concentration and a ratio in the “island of the stationary states” evolves down and to the left of this zone. The analysis in the $^{26}\text{Al}/^{10}\text{Be} = f([^{10}\text{Be}])$ diagram of the data obtained from the samples therefore allows the determination of how long they have been buried. The time range that can be investigated using this burial dating method extends from about 0.2 Ma up to 5 Ma.

This burial dating method has most notably been applied to sedimentary layers containing fossils and/or artifacts of paleo-anthropological interest (Partridge et al. 2003; Balco and Rovey 2008; Granger et al. 2015).

Uranium-Series

DIRK L. HOFFMANN

Max Planck Institute for Evolutionary Anthropology,
Germany

Uranium (U) is a chemical element with atomic number 92—that is, the nucleus contains 92 protons—which is part of the actinide group of the periodic table. There are three main naturally occurring U isotopes (^{238}U , ^{235}U , and ^{234}U) (see ISOTOPES), all of which are radioactive. ^{238}U and ^{235}U are starting isotopes (parents) of so-called decay chains, where a series of decay products (daughters) are also radioactive. There are three such decay chains; each starts with an actinide nuclide (the third decay chain starts with ^{232}Th) and ultimately ends with a different stable isotope of lead (Pb). ^{234}U is part of the ^{238}U decay chain, which is partially shown in Figure 1.

U and its daughter nuclides (U-series) are commonly used in geosciences as tracers or as a chronological tool, a good overview of different applications of which can be found in Bourdon et al. (2003). This entry here focuses on U-series dating, in particular $^{230}\text{Th}/\text{U}$ (or U-Th) dating, which is the most important application for archaeological sciences (see DATING IN ARCHAEOLOGY).

Generally, the temporal evolution of the activity ratio between ^{230}Th and U (^{238}U and ^{234}U) provides a timer for the time elapsed since a constrained fractionation. In an undisturbed material, all radioactive daughter nuclides of the decay chain reach a steady state of radioactive equilibrium with the parent nuclide. In other words, in rocks that formed millions of years ago we find the same activity for all daughter nuclides (except the final Pb isotope). However, natural processes such as dissolution or leaching of host rock can disrupt the state of equilibrium between the activity of parent and daughter isotopes, because U is soluble in natural waters, whereas Th is largely insoluble in natural waters. The same principle applies to ^{231}Pa and its parent ^{235}U of the ^{235}U decay chain, because Pa is also insoluble.

As a consequence, ground waters, rivers, and seawater contain dissolved U but essentially no Th (or Pa), and, in contrast to U, Th (or Pa) is not incorporated in secondary carbonates which precipitate from these waters, resulting in an initial $^{230}\text{Th}/\text{U}$ (or $^{231}\text{Pa}/^{235}\text{U}$) disequilibrium.

This applies, for example, to marine carbonates like reef and deep-sea corals or terrestrial carbonates like speleothems (see CAVES AND FISSURES). The initial concentration and hence activity of ^{230}Th in the carbonates, $(^{230}\text{Th})_{\text{init.}}$, is zero, which means that the U-Th “timer” is reset and immediately started again due to the presence of U. In the case where carbonate remains closed thereafter (i.e., both U and Th isotopes are neither lost nor gained), the development of $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$ is described by equations (1) and (2) (see Ivanovich and Harmon (1992) for derivation):

$$\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)(t) = \left(\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_{\text{init.}} - 1\right) e^{-\lambda_{234}t} + 1 \quad (1)$$

$$\begin{aligned} \left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right)(t) = & (1 - e^{-\lambda_{230}t}) \\ & + \left(\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)(t) - 1\right) \\ & \frac{\lambda_{230}}{\lambda_{230} - \lambda_{234}} \left(1 - e^{-(\lambda_{230} - \lambda_{234})t}\right), \end{aligned} \quad (2)$$

where $(^{234}\text{U}/^{238}\text{U})_{\text{init.}}$ is the initial $(^{234}\text{U}/^{238}\text{U})$ activity ratio and λ_i are the decay constants for ^{230}Th and ^{234}U , respectively. However, equations (1) and (2) are only valid if two fundamental conditions are fulfilled: (1) there is no presence of initial ^{230}Th ; and (2) the system remains closed after deposition. If so, the measurement of present-day $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$ allows the iterative calculation of the time since the formation of the mineral. Figure 2 shows the temporal development of $(^{230}\text{Th}/^{238}\text{U})$ for the simplest case where $(^{234}\text{U}/^{238}\text{U})_{\text{init.}} = 1$. As a rule of thumb, equilibrium is reached again

Figure 1 Schematic drawing of the ^{238}U decay chain. Small circles indicate short-lived intermediate decay products. Relevant half-lives of decays are given in the arrows.

Figure 2 Temporal evolution of the $^{230}\text{Th}/^{238}\text{U}$ activity ratio (for the simplest case with $^{234}\text{U}/^{238}\text{U} = 1$) after Th was removed from the system.

after 500–600 ka (thousand years) which is the limit for this dating technique.

Using the $^{230}\text{Th}/\text{U}$ method it is possible to date the time of precipitation of speleothems like stalagmites, stalactites, flowstones, and CaCO_3 crusts. It can also be applied to open-air spring deposits such as travertine and tufa, although these typically show a relatively high degree of

dirt inclusion, so-called detritus, which usually violates the first fundamental condition of no initial Th. In some cases, $^{230}\text{Th}/\text{U}$ dating is applicable to lacustrine carbonates, or—with caution—to some biogenic materials such as bones, teeth, molluscs, and egg shells, although these are known to be an open system for U and therefore require a suite of analyses at high

spatial resolution (e.g., using laser ablation techniques) to assess potential U mobility. U uptake or loss assumptions are then used for a model age calculation.

Dating of CaCO_3 formation can provide important age constraints for associated archaeology (see ARCHAEOLOGICAL RECORD). Flowstones in caves, for example, are often found in a stratigraphic relationship to archaeological excavations and can be used to constrain the age of underlying (minimum age) or overlying (maximum age) sediments. Speleothems like broken stalagmites and stalactites, specifically so-called straw stalactites, are frequently found inside excavated sediments. These speleothems formed before they were buried in the sediments and thereby can serve as a maximum age constraint for the associated layer. Dating of a post-sedimentation precipitate, which can occasionally be found in sediment voids, provides a minimum age for the surrounding sediment accumulation. In some cases, CaCO_3 precipitated on the surface of archaeological artifacts, for example on skeleton bones. $^{230}\text{Th}/\text{U}$ dating of the CaCO_3 coating on the bone surface provides a minimum age for the archaeological find. The same principle applies for $^{230}\text{Th}/\text{U}$ minimum age constraints for paleolithic cave art derived from CaCO_3 crusts that formed on top of the art. Where cave art is found on a speleothem formation, dating of the underlying CaCO_3 can also provide a maximum age.

Applications of U-series dating in archaeology are not restricted to cave sites. Archaeological finds are also frequently found, for example, in relation to travertine formations. Where a stratigraphy of the travertine and the archaeology can be established, U-series dating can be used as a chronological tool as well. Unfortunately, direct U-series dating of biogenic material like bones and teeth, often found in archaeological sites, is an exception since these materials are usually open systems.

$^{230}\text{Th}/\text{U}$ dating requires precise and accurate measurement of the relevant U and Th isotope abundances to obtain the isotope activity ratios needed to calculate an age according to Equation (2). The isotopes ^{238}U , ^{234}U , and ^{230}Th decay by alpha emission (Figure 1) and have different atomic masses, and thus two methods are commonly used for U and

Th isotope measurements: alpha spectrometry and—more precise—mass spectrometry (MS). Both techniques require prior chemical separation and purification of U and Th from the CaCO_3 matrix. Since U and Th behave differently during chemical separation and purification treatment, a tracer is required, which is a solution with known accurately calibrated concentrations of noncommon U and Th isotopes, for example ^{233}U , ^{236}U , and ^{229}Th . A defined quantity of the tracer needs to be added to the sample prior to the separation procedure (so-called isotope-dilution technique).

Most precise and accurate U-Th isotope ratio measurements can be done with multiple collector (MC) MS (see MASS SPECTROMETRY (MS)) techniques, such as thermal ionization mass spectrometry (TIMS) and inductively coupled plasma mass spectrometry (ICPMS). Generally, state-of-the-art MC-ICPMS techniques require smaller sample sizes and provide the highest precision. For $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$, precision in the range of 1–2 ‰ can typically be achieved and the limit for $^{230}\text{Th}/\text{U}$ -dating is in the range of approximately 600 ka. Precision of the U-Th dating depends on the age of the sample: a sample with an age around 100 ka can be dated with a precision of several per mille (i.e., several hundred years); samples with an age older than 400 ka and U-series activity ratios close to secular equilibrium have dating uncertainties of several percent.

The required CaCO_3 sample sizes for U-Th dating depend on the U concentrations in the material to be analyzed. Most carbonates have U concentrations larger than 10 ng/g, and in most cases 10–100 mg CaCO_3 are sufficient. ^{230}Th concentration in secondary carbonates is variable in time as it is not present when carbonate forms and then starts to build up. Therefore, the sample size needed for precise ^{230}Th measurement depends on U concentration and age of the sample; in most cases, a sample size between 10 and 100 mg is still sufficient.

The reliability of U-Th ages strongly depends on the closed system of the dated material and negligible initial ^{230}Th . Presence of initial (or detrital) Th is tested by determining the concentration of common Th (^{232}Th) in the sample. In the case of significant amounts of ^{232}Th , a correction for initial ^{230}Th needs to be applied.

This is based on a detrital $^{230}\text{Th}/^{232}\text{Th}$ activity ratio—for example, measured on an insoluble detrital fraction. The detrital $^{230}\text{Th}/^{232}\text{Th}$ can also be constrained by a so-called isochron, which is derived from measurements on a set of coeval subsamples. In the absence of such constraints, the detrital correction is done using a so-called bulk earth value of the upper continental crust.

A single U-Th age does not provide any information on whether the dated material represents a closed system or not. The most rigorous reliability test for a U-Th date is to employ the alternative ^{235}U -series and measure $^{231}\text{Pa}/^{235}\text{U}$ in addition to $^{230}\text{Th}/\text{U}$ on the same material. In the case of an open system, the two independent decay chains will be disturbed to different levels, and U-series ages will not yield the same result. With concordant U-Th and U-Pa ages, confidence can be placed in accuracy of the results. However, U-Pa cannot be determined to the same degree of precision as U-Th and small deviations may not be detected. U-Pa analyses also require much larger sample sizes due to a significantly smaller abundance of ^{235}U ($^{235}\text{U}/^{238}\text{U}_{\text{conc}} = 0.0073$) and thus cannot be employed in many cases. Therefore, it is usually recommended to perform repeat $^{230}\text{Th}/\text{U}$ analyses where open systems cannot be excluded. Stalagmites, flowstones, or other carbonates that form with internal stratigraphic constraints provide an additional possibility to check reliability, since ages of subsamples along the growth axis must become progressively younger from bottom to top.

Varve Chronology

BLAS L. VALERO-GARCÉS

JUAN PABLO CORELLA

Institute of Physical Chemistry Rocasolano, Spain

History of “varve chronology research” and current methodologies applied in varve sequences

Varves are defined as finely laminated sediments that occur in aquatic environments with an annual cycle of deposition. The term “varve” (Swedish: *varv* meaning layer) was originally introduced by the Swedish geologist Gerald De Geer for glacio-lacustrine sediments. He suggested that varves represented annual cycles, with silt layers deposited during the melting season while finer, clayey sediments settled in winter when the lake was ice-covered. De Geer (1912) demonstrated, for the first time, the use of varve counting as a chronological tool in ice retreat history. Since his pioneering work, many other scientists have tried to achieve high-resolution chronologies by counting rhythmic sediment layers. For example, varve researchers in the 1920s used the “varve” concept of De Geer to quantify sedimentation rates in Lake Geneva by counting rhythmic layers that were thought to be annual. Four decades later, the onset of radiometric dating demonstrated that the lamination reflected deposition of irregularly distributed clastic layers that did not respond to annual cycles.

This raises important issues regarding the procedures to assure robust chronologies using laminated sediments. First, in order to develop an adequate varve-based chronology, a preliminary depositional conceptual model describing the structure and annual nature of the sediment cycles is needed. Second, the methodology and error estimation techniques applied to obtain the varve age-depth model should be

carefully selected depending on the varve’s quality, nature, composition, and thickness. Several methodologies have been used and tested in the varve community during recent decades. Thick varves can be counted by detailed visual inspection of cleaned fresh sediment and from high-resolution photographs from cores of open halves. Thinner varves require further microscopic investigations. Unconsolidated sediments are embedded with epoxy resins to obtain polished blocks that allow thin section preparation to perform high-resolution microfacies analyses and varve counting. The recent development of efficient computer-based image analysis has also resulted in a third methodology based on automated or semi-automated varve counting from digitalized varve sequence photographs. Geochemical analysis (mostly based on micro X-ray fluorescence (μ XRF) core scanner techniques) can also provide additional support for varve age determination based on the distinct elemental composition of the different layers. This technique is useful when varve differentiation is not clear by visual and/or microscopic investigations. Quantification of errors in varve chronologies based on replicated varve counts on multiple cores, ideally carried out by independent experienced researchers, is also a requisite to achieve reliable age-depth models. Finally, a validation of the varve age-depth determination should be achieved by comparison with other independent dating methods (e.g., ^{14}C , ^{210}Pb , and ^{137}Cs radiometric dating, palynological stratigraphies, tephrochronology, paleomagnetism) that would reveal the accuracy of the varve chronology. If extended to the present day including recent surface sediment, varve chronologies can be regarded as absolute, that is, representing a calendar-year timescale. On the other hand, if the varve sequence has intervals without preservation of annual cycles due to changes in the depositional and limnological dynamics, the varve chronology is defined as floating. In these cases, researchers use marker-horizons related to well-known historical or environmental events to anchor the chronology.

Varve types

The formation and composition of varves is governed by a suite of climatological, hydrological, limnological, and biological processes. Although there is not a unique environment leading to the formation of varves, they mostly occur under anoxic bottom conditions that impede bioturbation and burrowing activities that may disturb the laminations. Varves are composed of sets of laminae deposited during different seasons within the annual cycle, and, consequently, strong environmental seasonality is also required to create these laminated deposits. Three main types of varves are reported in the literature:

- Clastic varves, such as the glacio-lacustrine varves originally described by De Geer (1912). They respond to physical processes (e.g., freeze–thaw annual cycles) and are mostly composed of mineral detrital particles of different grain sizes.
- Biogenic varves, whose formation is mostly governed by biological processes. Among the different biogenic varves, calcareous varves are the most common, characterized by seasonal bio-induced precipitation of calcium carbonate related to algal blooms.
- Evaporitic varves, controlled by variable physico-chemical processes that modulate the seasonal precipitation of carbonate and sulfate mineral phases. These varves are less common and occur in arid and semi-arid regions.

Spatial distribution of varve sequences

Varve sequences occur in a wide range of depositional environments (mostly in marine, estuarine, and lacustrine settings). A recent review of geographic settings and varve chronologies shows an irregular worldwide distribution (Ojala et al. 2012). A total of 99 lacustrine varve sedimentary sequences with reasonably robust varve chronologies were reported. These researchers excluded varve chronologies with temporal extension of less than 100 years, since many modern varve settings show varve precipitation as a result of modern anthropogenic eutrophication during the

last decades. A global compilation of Quaternary marine varved sedimentary records reported 52 sites (Schimmelmänn et al. 2016). These global varve-based chronologies highlighted the heterogeneous spatial distribution of varve settings. Marine varves have been mostly described in the northern hemisphere. Similarly, lacustrine varve chronologies are more widespread in Europe and North America. Marine varves have mostly been documented close to the continent, although they also occur in deep-sea environments and display different temporal intervals. On the other hand, varves preservation is favored in lacustrine basins with meromictic conditions—that is, permanent anoxic hypolimnion—sheltered from the wind. Maar lakes, deep tectonic basins, and karstic lakes provide examples of potentially good sites for varve formation and preservation.

Quaternary varve chronologies: the example of Lake Suigetsu

Most of the lacustrine varve chronologies are constrained to the Late Holocene. Only a few records extend to periods before the onset of the Holocene, such as the Central European lakes Holzmaar and Meerfelder Maar. However, the longest lacustrine varve chronology to date comes from Lake Suigetsu in central Japan. The sediments in this tectonic lake include biogenic and clastic varves deposited over the last 70,000 years. This varved sequence has been studied by numerous researchers since the early 1990s due to its high potential to provide a terrestrial radiocarbon calibration model. The development of a robust varve chronology in this lake would eventually result in a high-resolution chronology of paleoclimatic changes that could be compared to other key climate records worldwide. After two decades of detailed sedimentological and geochemical analyses carried out by researchers from different institutions, the varve chronology has served to calibrate and complete a terrestrial radiocarbon chronology beyond the tree ring limit for the period 11.2–52.8 kya (Ramsey et al. 2012). The achievement of a calibration of the terrestrial radiocarbon curve for the last 50,000 years has obvious implications not only for paleoclimate

research but also for paleoanthropological and geoarchaeological studies.

Varves as a paleoenvironmental proxy for archaeological studies

Since the time of De Geer, but especially since the end of the 1990s, varve researchers have tried to link environmental conditions reconstructed from varve sequences to human societal evolution. The high-resolution climate and environmental information contained in these records has been used by paleoclimatologists and archaeologists to evaluate their effect on the rise and demise of humankind during the last millennia. One of the best-known examples is the anoxic Cariaco Basin in the southern Caribbean Sea, which preserves clastic and biogenic varves deposited during the last 1,500 years. The seasonally resolved chronology coupled with geochemical measurements based on the titanium content in the sediment as a proxy for riverine input has allowed the reconstruction of regional rainfall changes (Haug et al. 2003). These authors suggested that centennial-scale decline in rainfall led to a large regional drought, which played a decisive role in the collapse of Classic Maya civilization in the Terminal Classic Period. This varve sequence also provided a more refined temporal framework to compare archaeological-based chronologies.

Several lacustrine varve sites in the eastern and western Mediterranean have also shed light on the environmental forcings that influenced past human migrations. Lake Zoñar, a small karstic lake located in a semi-arid region in southern Iberia, provides a floating varve chronology composed of biogenic varves for the Iberian–Roman Humid Period (1600–2600 BP; Martín-Puertas et al. 2009). The paleohydrological proxies derived from this sequence revealed more humid conditions in southern Spain coinciding with the flourishing of the Iberian culture and the Roman Conquest. Lake Montcortès, another karstic lake located in northern Iberia (southern central Pyrenees), contains an absolute varve chronology spanning the last 2,800 years (Corella et al. 2016). Detrital layers embedded in the biogenic varve succession provided a seasonally-resolved rainfall

record from the western Mediterranean. An exceptional, centennial-long period with very low rainfall frequencies between 370 and 670 CE was synchronous to the collapse of agricultural-based societies at the end of the Roman Empire and the onset of Visigoth invasions. Several geochemical and biological indicators in these Iberian sequences point to relatively warmer and more arid conditions during Early Medieval times (somehow synchronous to the Medieval Climate Anomaly) compared to the post-fourteenth century (Little Ice Age). Varve chronologies are also available from eastern Mediterranean sites. Interestingly, the opposite hydrological signal was reconstructed from Lake Nar Gölü, a maar lake located in Cappadocia, central Turkey, with more humid conditions prior to 1500 CE. The Nar Gölü varve chronology spans the last 1,720 years. Dean et al. (2013) reconstructed the precipitation seasonality in the region using stable isotopes ($\delta^{18}\text{O}$) in diatoms and carbonates. Harsh winters with increased snowfalls combined with dry summers resulting in a negative water balance were frequent between 301 and 561 CE. This marked seasonality may have led to a decline in agricultural-based societies in the Near-East. This see-saw pattern from the Mediterranean exemplifies the use of varve chronologies to determine the synchronicity of environmental changes and the consequences of human societies' evolution and migration patterns.

Unfortunately, varves are not always located in areas of great significance for anthropological and archaeological studies. The geoarchaeological community would greatly benefit if new “varved” sedimentary sequences are found in Africa and the southern hemisphere in order to increase the spatial resolution of these annually-resolved paleoenvironmental archives. An example is the 25-ka sedimentary sequence from crater Lake Challa (Kenya/Tanzania) located on the eastern slopes of Mount Kilimanjaro and with an absolute varve chronology for the last 3,000 years and a floating varve chronology during the Last Glacial Period (Wolff et al. 2011). As the thicknesses of the biogenic varves were directly related to rainfall dynamics, interannual to centennial-scale changes in ENSO-related rainfall patterns that had controlled flooding and drought variability in the region could be reconstructed. These environmental changes had drastic impacts on

past human habitation and food security in eastern Africa. New varve-based chronologies and paleoenvironmental, paleoanthropological, and archaeological research in this region will shed light on past environmental–human interactions in the cradle of humankind.

Future research coupling varve and archaeological studies will play a key role in the human–climate–environmental debate, including the influence of water availability on past human migrations and evolution, and/or the influence of catastrophic events (such as major earthquakes, storms, droughts) on human societies during the last millennia.

Air Pollution

SIMON TURNER

University College London, UK

Air pollution is the perturbation of atmospheric conditions, through inputs of materials and energy, overwhelmingly owing to human activity. Air pollution parallels the evolution of human industrial activity: the extraction and conversion of global resources for capital gain, with indifference (until comparatively recently) to the fate of the waste expelled into the atmosphere. Global industrialization, fossil fuel combustion, and technological innovation have changed the natural variations in atmospheric conditions and composition to the present interlinked human-atmospheric global system (Steffen, Crutzen, and McNeill 2007). Air pollution has become a society-driven, planetary process capable of being detected across interstellar space (Stevens, Forgan, and O'Malley James 2016).

Air pollution requires a source and mechanism of atmospheric dispersal, followed by a process of contamination concentration that has a distinguishable effect on human and natural systems. Simple source, sink, and effect concepts are complicated by chemical reactions in the atmosphere that convert primary pollutants into secondary pollutants. Primary pollutants are directly emitted from sources, including sulfur dioxide (SO_2), nitrogen dioxides (NO , NO_2 commonly referred to as NO_x), volatile organic compounds (VOC) such as hydrocarbons, including methane (CH_4), carbon monoxide (CO), and metal compounds. Secondary pollutants are a range of gases, particulates, and aerosol mixtures created by the interaction between primary pollutants and atmospheric processes, for example the photodissociation of industrial emissions of chlorofluorocarbons into ozone (O_3)-depleting substances and a chain of reactive intermediates between mixtures of both primary and secondary pollutants.

Contrasting effects also occur with some atmospheric pollutants. For example, the sulfate aerosols from fossil fuels contribute to acid rain but also cause atmospheric cooling by reflecting solar radiation back into space. Local and regional temperature change due to human activity (vegetation patterns, urban development) should also be considered as air pollution, not least because of its co-effect with other pollutants on mortality rates due to high temperatures (Willers et al. 2016).

Early human activity largely replicated sources of natural atmospheric contamination through burning for hunting, fuel use, and land clearance for agriculture (see ENVIRONMENTAL MANAGEMENT WITH FIRE). Emissions of gas and dust from volcanic activity (see ARCHAEOLOGICAL VOLCANOLOGY) during the Holocene had effects, from local to global (tropospheric cooling, shading, acid deposition), that were not observed until the Industrial Revolution. Poor domestic air quality and increased mortality caused by inadequate ventilation, low-grade fuels, and inefficient fuel combustion would have been common in early fire use and remain global problems (WHO 2014). The physical unpleasantness of sitting in a smoke-filled interior (balanced nonetheless with the benefits: warmth, reduction of biting insects) would have been a driving factor in technological advances such as the development of the chimney. Early industrial methods of ore extraction and refinement led to both more advanced furnace techniques and emission products being deposited locally and globally, with direct and indirect impacts on human and ecological communities. Evidence for early industrial air pollution alone having an effect on human mortality rates is restricted, owing to (a) other factors detrimental to human health (domestic air quality, disease, subsistence); (b) the range of other pathways (ingestion of contaminated water, foodstuffs grown on waste contaminated soil) that also determined biogeochemical intake; and (c) taphonomic factors (see TAPHONOMY).

Classical Greek and Roman, then Arabic, Chinese, and early European writers noted and

discussed the degradation of health due to the poor air quality that accompanied the growth of towns and cities and the concentrated use of biomass fuels (wood, crop residues, dung, and coal). Air pollution, however, radically changed with the unprecedented social and economic changes of the Industrial Revolution and the widespread use of coal for industrial and domestic fuel. Atmospheric concentrations of sulfur, soot, smoke, and other industrial emissions increased in towns and cities, along with a population that came to work with steam-powered engines and other technological developments from manufacturing. Definitive skeletal or pathological evidence of increased mortality, during this period, from air pollution alone is, however, scarce, even where there are contextual and historical indications of occupational and diffuse exposure to poor air quality (DiGangi and Sirianni 2016; Roberts et al. 2016).

The combination between an increased population density and the understanding of disease vectors and obvious signs of poor air quality (visible smoke, soot, corrosive damage to buildings) prompted early attempts at statutory air-quality legislation that clashed with economic progress. Throughout the nineteenth and early twentieth century, in cities and towns in the United Kingdom and other rapidly urbanizing countries, the demands for production and wealth generation were greater than any response to air pollution and its impact on ecosystems and human health. Although some correction occurred through improved working conditions, combustion technology, and the dilution of emissions due to urban expansion, air quality continued to deteriorate. Severe smoky fogs (smogs) in densely populated areas coincided with the high mortality rates that finally gave momentum to legislature such as the Clean Air Acts (UK, 1956, 1968) and Air Pollution Control Acts (USA, 1955, 1963). These, along with technological and social changes, reduced much of the local- and regional-scale negative effects of air pollution by the mid-twentieth century. Due to the colossal twentieth-century population growth and planetary demand for energy, which could be sustained only by fossil fuels, air pollution in the mid- to late twentieth century became widely recognized as a global phenomenon. Air pollution issues such as the acidification of rain and surface waters through

SO₂ and NO_x, the depletion of polar stratospheric ozone as a result of chlorofluorocarbons, and the deposition of fossil fuel-associated toxic metals into ecosystems were identified with the help of scientific advancements in atmospheric chemistry, environmental monitoring and modeling, and paleoenvironmental research. More rapidly and effectively than in the mid-nineteenth to early twentieth century, a scientific understanding of the processes involved the ability to implement technological solutions (e.g., flue gas desulfurization at power plants); and international political agreements allowed these issues to be “solved,” significant recovery having been achieved in many affected ecosystems. During the same period and up to the present, fossil fuel combustion, automobile emissions, and agriculture have greatly increased the atmospheric concentrations of carbon dioxide (CO₂), methane, and other greenhouse gases.

The challenge of measuring air pollution levels in the past is that of distinguishing and quantifying the material evidence for time-specific atmospheric contaminant loads. Information on past atmospheric contaminants released through human activity over millennia can be obtained from ice core, marine, and high-altitude lake sediment and peat sequences. Types of fuel combusted, gases released, and materials processed are identifiable by means of compositional (e.g., pyrogenic carbon: Thevenon et al. 2010) and isotopic (e.g., ^{206/207}Pb, $\delta^{13}\text{CH}_4$, $\delta^{15}\text{N}$) measurements. With good chronological control both in the depositional archive and in contexts from areas of industrial release, variations in the magnitude and composition of the contaminants released can be matched (Rosman et al. 1997) and an estimate of past air pollution levels be made.

Records of atmospherically transported trace contaminants in remote environmental archives provide a clear signal of increased atmospheric contaminants, but evidence of local air pollution requires more detailed, site-scale investigation. Evidence from early metal-working centers—in the form of skeletal metal levels, volumes of furnace waste, contaminated soils, and sediments contemporaneous with the operation and paleoecological evidence of vegetation changes—indicates that air pollution would have been prevalent and considerable (e.g., Grattan et al. 2016). At early industrial sites,

however, quantifying past concentrations and trends of atmospheric contaminants is limited by the lack of depositional contexts that preserve time-constrained atmospheric loadings. Taphonomic processes are also critical factors affecting the fossil composition of particles and of products derived from atmospheric deposition. The nature of fuel-combustion products (ash, charcoal) in urban and industrial cultural layers is determined by the distance of the sampling site from the source and by the nature of combustion (fuel type and intensity). There are multiple pathways by which atmospherically transported materials can accumulate in archaeological contexts and in environmental systems that are asynchronous when it comes to the timing of contaminant inputs, including catchment erosion/remobilization and postburial diagenesis.

Evidence of preindustrial atmospheric conditions also comes from preserved crusts on stone monuments and architecture. Like modern crusts on stonework containing high-temperature fossil fuel combustion products, preindustrial crusts contain evidence of lower-temperature wood and charcoal combustion products (Del Monte et al. 2001). Such archaeometric methods are dependent on known exposure periods and on similar taphonomic considerations that apply to detecting combustion products in cultural deposits.

Comparison between proposed atmospherically derived contaminants in archaeological layers and synchronous off-site environmental archives is recommended. Methods developed to assess recent historical atmospheric pollution loads (e.g., spheroidal carbonaceous particles [SCPs], polyaromatic hydrocarbons, trace metals, Pb and N isotopes in lake sediments) can be applied to long-time scales but some, SCPs in particular, are only a consequence of high-temperature fossil fuel combustion unseen until the Industrial Revolution (Rose 2015).

Although dwarfed by the global effects of anthropogenic climate change, air pollution remains a huge and growing health issue, 7 million deaths being annually attributed to it (WHO 2014). Domestic, occupational, and outdoor pollution levels far exceed international health guidelines for NO₂, PM₁₀, and PM_{2.5} (particle matter <10 and 2.5 microns) in many developing nations, especially in African, Indian, and

Chinese cities, given the expanding numbers of both people and vehicles. In developed nations, gases (O₃, NO_x) and particulates from industrial and vehicle emissions remain at chronic levels in many cities, causing ill-health and raised mortality rates (Samoli et al. 2016).

Archaeoentomology

DAVID SMITH

Birmingham University, UK

Archaeoentomology, or the study of insect (and other arthropod) remains in the Pleistocene and archaeological record, contributes to three distinct areas of research:

- Climate, vegetation, and landscape reconstruction (see CLIMATE CHANGE AND DATING and VEGETATION MODELING USING POLLEN DATA)
- Establishing the impact and role of humans in landscape change (see ENVIRONMENT AND LANDSCAPE and INHABITED LANDSCAPES)
- The interpretation of the environment in settlements, the urban landscape, and associated archaeological deposits (see URBAN ENVIRONMENTS).

These studies investigate issues such as deposit formation, human health and hygiene, quality of food supply, the spread of storage pests and synanthropic species, and patterns of past human behavior.

Given the sheer diversity of arthropods (phylum Arthropoda) found in the modern world, the actual number of orders and classes studied archaeologically is surprisingly small, mainly consisting of a narrow range of insects and arachnids. This is due to the extent to which they are preserved in the archaeological record, their relative “interpretive yield,” and the ease of identification of a specific order. The major groups that are routinely studied are beetles (Coleoptera), true flies (Diptera), caddis flies (Tricoptera), true bugs (Heteroptera), bees, wasps, and ants (Hymenoptera), lice (Malophaga), fleas (Siphonaptera), mites (Acari), and nonbiting midges (Chironomidae).

Insect remains can be preserved in the archaeological record in a number of complex ways, meaning that insect death assemblages suffer

from a range of preservation, taphonomic, and selective biases (see FORMATION PROCESSES and TAPHONOMY). There have been various attempts to counter, or at least identify, these problems (Kenward 1978; Smith and Kenward 2012).

Normally, the exoskeletons of insects will disarticulate in the archaeological record into sclerites, but instances of semi-intact or even whole insects are not uncommon. The commonest form of preservation encountered is by anoxic waterlogging, which requires continued saturation of the deposit between deposition and sampling. Suitable deposits are therefore often limited to the “organic crescents” of the northern and southern latitudes where climate and ground water conditions allow waterlogged deposits to develop (Kenward and Hall 2008). Insect remains can be routinely recovered from a range of natural or naturally infilling deposits such as organic sedimentary layers, water channel, valley, and river fills (encompassing a range of reed, wood, and organic fluvial sediments), and peats (see PEAT DEPOSITS). In terms of settlement archaeology, the extent of waterlogged deposits often depends upon the nature of the past and contemporary water tables and how the settlement has developed over time. Equally, the digging of deep features such as ditches, wells, and cess pits to below, or close to, the water table can allow material to become waterlogged, even if the contemporary ground surface remains dry. Deeply stratified urban sites are also thought to become progressively waterlogged as water rises by “wicking” through the deep accumulations of organic material that build up. This can be the case even if the archaeology lies well above the geological water table (Kenward and Hall 2008).

Insects can be preserved through desiccation and freezing, where these conditions persist over time. Instances of insect remains being preserved through the deposition of organic salts (e.g., in packrat middens), carbonization, or by being sealed into deposits in such a way that oxygen is excluded do occur, but remain unusual modes of preservation. At some sites, insect remains also can be preserved by mineral replacement (see FORMATION PROCESSES).

Recovery, identification, and quantification

The main consideration in terms of sampling for insect remains is to obtain a representative set of material that is relevant to the research questions being posed (see *SAMPLING IN ENVIRONMENTAL STUDIES*). The analysis of Coleoptera and Diptera normally requires a 10-L sample of material if it is to be representative of the population being sampled. Samples are usually taken as continuous slices from an open section in order to assess how the insect assemblages change over time. Well-defined settlement or “natural” deposits are commonly sampled by taking material from each “layer” or context. At many sites, insect remains are recovered from “general biological samples” which are used to also recover plant macrofossils, pollen, and other biological remains (Kenward, Hall, and Jones 1980, 4). If it is not possible to gain access to an open face of a section for sampling, material can be obtained from multiple parallel cores using a Russian auger, though depth control can be problematic (see *CORING*).

Insect remains are normally extracted from sampled sediment using paraffin (kerosene) flotation. After the sediment has been disaggregated, paraffin is added to the material. The paraffin adheres to the chitinous sclerites and when cold water is added the insect remains should float to the surface. The material is then poured onto a 300- μ m-mesh sieve. This process, first established by Peter Osborne (University of Birmingham), is described fully by Kenward and colleagues (1980). Paraffin flotation has been found to be a reliable and efficient method for the extraction of insect remains from waterlogged material, often reaching levels of 80 percent recovery in experimental studies (Rousseau 2011). Other methods of extraction have been proposed, but these have been found to be less efficient (Rousseau 2011). Chironomids and mites have their own extraction methodology. Once a flot has been obtained, the paraffin adhering to the insect remains is removed by washing in detergent and the flot sorted to recover insect remains by hand under a low-power 10X–50X microscope. The resultant insect fragments are then sorted into “morphological groups” by the specialist.

The extraction of insect fragments preserved by other means requires a different approach. Desiccated, charred, and mineral-replaced remains that are greater than 300 microns in size will often need to be hand-sorted from flots or residues resulting from sieving the sample. It is often more efficient to have the paleobotanist pick out these insect remains as well as any plant remains present. At present, the identification of insect remains is mainly based on comparison of the archaeological specimen's gross morphology to modern reference material (see *USE OF BIOLOGICAL COLLECTIONS*), supplemented by the use of modern taxonomic guides, photos, and web-based illustrations. Features that can be useful for determination are general shape, surface microsculpture, and where the pore punctures (which in life hold the insect's sensory “hairs”) are located. Rarely, it may also be possible to identify insects from their genital armature.

Initial quantification of disarticulated insect remains usually occurs by conducting a minimum number of individuals (MNI) count. Fragmented remains of Coleoptera are usually quantified on the head, thorax (pronotum), and left or right elytron (wing case) elements. The minimum number of individuals for Coleoptera counted in this way, therefore, will be the highest score of one of these four elements (i.e., with 1 head, 2 thorax, 3 right elytron, and 2 left elytron; MNI = 3). Whole, or semicomplete, insects encountered (e.g., fly puparia and mites) are usually counted by identifying one specific “identification zone” (usually the posterior or anterior end).

The relative number of insect taxa within assemblages also can be recorded using a range of estimated counts (e.g., an abundance scale) rather than a full enumeration (see Kenward et al. 1985). This is especially useful during the assessment of the research potential of material, or on very large-scale urban sites where many of the insect assemblages recovered from different contexts can be essentially highly similar. Though not statistically proven, it seems very little information is lost by using such estimated counts. It also has become quite common practice to semiquantify archaeoentomological material from urban deposits, where the material is “scanned” for a set period of time (normally 10–15 minutes) to establish its range and diversity.

Analysis

The basic and underlying assumption of insect analysis is that a species' modern ecology will essentially be the same in the past as it is today, thus allowing a straightforward paleoenvironmental reconstruction to occur (e.g., Coope 1977). It has been established that for at least the last one million years, there has been little morphological or physiological evolution of insects in the northern hemisphere, although the distribution of different species has varied greatly (Coope 1977). The first level of insect analysis, therefore, is to obtain known modern ecological information about a taxon, such as temperature range tolerated, ecological behavior, and food preference. This allows specific species identified in an archaeological assemblage to be used as "indicator species" for particular environments, materials, and/or human behaviors (e.g., the "granary weevil" *Sitophilus granarius* is treated as a direct indicator for the presence of grain).

This assumption underpinned Russell Coope's initial attempts at climatic reconstruction using the modern temperature "envelopes" of a number of key species from Pleistocene deposits (Coope 1977). This process subsequently has been refined and elaborated by the use of the "mutual climatic range" model (Atkinson, Briffa, and Coope 1987).

In terms of landscape and environmental reconstruction, initial attempts to use the proportions of indicator species to provide reconstructions of environments, landscapes, and archaeological sites (the so-called mosaic approach) proved problematic. Mainly this is due to a number of biases inherent in the nature of both the formation of insect assemblages and the archaeological record itself (Kenward 1978).

Subsequently, there have been attempts to investigate the nature of insect faunas using combined ecological groupings and a range of multivariate statistics to identify and counter these effects (e.g., Carrott and Kenward 2001; Smith and Kenward 2012) (see also CORRESPONDENCE ANALYSIS and STATISTICS IN ARCHAEOLOGY). In terms of settlement archaeology, recent developments have established that the combining of insect "indicator groups" into larger interpretative "indicator packages" is a useful interpretative tool for a range of biological and archaeological

phenomena (e.g., Kenward and Hall 1997). This has proven to be a successful approach to archaeological interpretation, allowing materials such as stable waste, roofing thatch, craft materials, and sewage (all deposits that share materials such as cereal straw, but with the straw used in different ways) to be identified with some confidence.

Future research and prospects

There is a clear need to increase the range of insects that are routinely studied. Several orders of insects and other classes of arthropods have great potential to function as environmental proxies or archaeological indicators, but they remain underutilized or underinvestigated (for example, the limited use of true flies, caddis flies, and mites).

The study of insect remains is mainly constrained for historical reasons to northern Europe, where the discipline first developed, with limited forays into North America, the Mediterranean, and Eurasia. There is clearly enormous potential for this discipline to develop worldwide.

There continues to be a shortage of trained practitioners in terms of both research and archaeological consultancy work, which constitutes a real threat to the discipline's future. Many of the assumptions and analytical techniques used in the discipline require thorough testing through calibration work, where modern insect faunas collected from a range of materials, landscapes, and deposit types can be compared to the faunas seen in the archaeological record. Additionally, biomolecular techniques are worth exploring, including stable isotopes (see ISOTOPES) and aDNA analysis (see SEQUENCING DNA and DNA: NEXT GENERATION SEQUENCING), in order to investigate the origins and distribution of insect species over time.

Archaeological Volcanology

MARK D. ELSON

University of Arizona, USA

MICHAEL H. ORT

Northern Arizona University, USA

The definition of *archaeological volcanology* can be simply stated as *the science of human adaptation to disasters arising from volcanic eruptions*. As its name implies, archaeological volcanology combines archaeology, a subfield of anthropology or history, and volcanology, a subfield of geosciences. The combination is necessary to understand how humans respond and adapt to volcanic eruptions, and data from all eruptions, from the past to the present, are used in this endeavor. As ethnographic, archaeological, and volcanological data attest, volcanic eruptions can act upon cultural groups as catalysts, as processes, and, rarely, as termination factors (Bawden and Reyecraft 2000; Cooper and Sheets 2012; Gaillard and Dibben 2008; Grattan and Torrence 2007; Ort et al. 2008; Riede 2015; Sheets and Grayson 1979; Sigurdsson 2015). Archaeological volcanology is related to the anthropology and sociology of disaster, as well as to hazards research and management. Volcanic eruptions are just one type of “hazard” that, when combined with an affected human population, can rapidly become a “disaster” that must be dealt with for both individual and group survival.

Volcanic eruptions are some of the most powerful natural phenomena, with their impact on the cultural and natural environment extending far beyond the zone of physical destruction. An eruption is a full sensory experience—these features are seen, heard, felt, and smelled. Eruptions shake the ground; create and sometimes destroy mountains; turn day into night; emit foul-smelling sulfur and other noxious gases; and make roaring, hissing, and knocking sounds that can be heard for hundreds of kilometers.

They are also highly symbolic, emitting red-hot glowing lava from deep within the Earth. As it cools, the lava transforms from a molten liquid to solid rock, which, along with the deposition of tephra (broken pieces of magma thrown into the air), can dramatically alter the landscape, cover long-established territorial markers, and alter or even destroy once-reliable water sources. Prior to the Industrial Age, the world was a quiet place, with a short clap of thunder being the loudest sound regularly heard, and the prolonged roar of an eruption would have been highly alarming and potentially terrifying. Unlike many other natural hazards, volcanic eruptions have an extended duration and can also evolve over time, making human adaptation not only an ongoing process, but one that must be flexible.

As a result of these impacts, volcanoes are well known as destructive to humans, animals, plant life, and property, which may account for the deep-seated fear and awe that characterizes the human–volcano relationship. Eruptions are common in traditional (or oral) histories, generally involving fires and molten rock from deep within the Earth, a place, for many societies, where both gods and people originated. It is not surprising, then, that eruptions are almost always seen as malevolent and often a form of divine punishment or retribution. What is less well known is that eruptions can also have very beneficial effects. Volcanic rock is a prime source for construction material. A thin tephra cover can also serve as a water-retaining, temperature-regulating mulch, allowing areas previously too dry to farm to become productive; bumper crop yields are often reported in areas with less than 15–20 cm of tephra in the years immediately following an eruption. Perhaps most significantly, areas once uninhabitable due to thick tephra cover may gradually transform into fertile agricultural fields. Volcanic soils today support a large proportion of Earth’s population.

One of the difficulties in dealing with a volcanic eruption, both as a disaster and as a research area, is that eruptions have both direct (short-term) and indirect (long-term) effects.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0041

These can combine (and recombine) in complex ways, and the addition of human cultural variables adds to the difficulty in deciphering these relationships. Direct effects can include death and injury, the destruction of villages and agricultural fields, forest fires, lahars (debris flows), earthquakes, and tsunamis. Indirect effects can include acid fog and rains, cooler temperatures, air pollution-related respiratory issues (see AIR POLLUTION), famine, vegetation destruction (and reduced rate of regeneration), loss of animal habitat, and the removal of large portions of previously productive landscape from human use. Because volcanoes are found across the world and have global effects, they also have the potential to impact different types of societies with varying degrees of social complexity, hierarchy, leadership, religious practices, subsistence systems, community organization, and kinship systems, and who live in a wide range of environmental settings. Even with this extreme variation, recent archaeological volcanology research has suggested that patterned similarities in both the nature of the volcanic eruption and the resulting human adaptation can provide insight into these processes. This research makes clear that to survive and successfully adapt to a volcanic eruption, affected populations need to employ cultural mechanisms that allow for both multiple short-term responses and long-term strategies.

Volcanoes

Volcanoes are the places where magma reaches the surface of the Earth. Volcanologists have classified volcanoes into several different types: scoria (or cinder) cones, maars, shield volcanoes, and stratovolcanoes. However, each eruption, no matter the type of volcano, is unique, and the resulting human response is dependent on the mix of a large, and often unpredictable, set of cultural and natural factors. Large stratovolcano eruptions are the type most familiar to the public. However, the smaller scoria cones and maars are the most common volcanic landform on Earth and the type most likely to impact human groups.

The types of eruption and volcanic landforms associated with them strongly affect the hazards presented by volcanic events and the adaptive processes that affected populations need to employ.

Magma vary greatly in their characteristics. Two very important parameters, magma viscosity and water content, can vary by at least ten orders of magnitude and from around 0 to 8 percent by weight, respectively. These dramatically affect how eruptions proceed—higher water and gas content causes the magma to vesiculate and increase in volume, which in turn increases its surface ascent rate but also causes it to break apart into pieces (pyroclasts). Higher viscosity leads to more explosive breaking of the magma if it is gas rich, and to steeper and less stable volcanic edifices if it erupts as a gas-poor lava.

Low-viscosity magmas (e.g., basalt) allow dissolved gases to escape quickly. Thus, they can produce lava that pours rapidly from the vent or fountain a few to tens of meters into the air before falling and forming lava flows. With somewhat higher viscosities and gas contents, similar magmas can shoot hundreds of meters into the air and produce large (to around 400 m high) piles of pyroclasts around the vent, forming a scoria cone. Less commonly, these eruptions produce columns that rise 5–15 km into the air, similar to many stratovolcanic eruptions. In some cases, basaltic magma interacts with groundwater, flashing that to vapor and exploding to form nuclear-bomb-like craters called maars. These explosions can dramatically affect areas a few kilometers from the vent. Basaltic eruptions tend to be less explosive than other types of eruptions, but the landforms they create (lava flows, broad low-angle shield volcanoes, and scoria cones) are amenable to human occupation, so people often live very close to the eruption sites and may learn to interact with the volcano. Scoria-cone and maar volcanoes usually only erupt once from the same vent for a week to a few years. Large volcanic fields, however, such as the Michoacán–Guanajuato Volcanic Field in central Mexico, can contain hundreds of scoria cones, making entire regions volcanically active and potentially hazardous.

Stratovolcanoes, such as Vesuvius, Fuji, and Mt. St. Helens, are perhaps the most iconic volcano landform. The andesitic to dacitic magma is typically more viscous and gas rich than basalts, leading to more explosive eruptions and thicker lava flows that pile up to form steeper edifices. These volcanoes can produce large pyroclastic eruption columns containing broken chunks of

vesiculated magma that can rise to a height of 30 km and deposit tephra over tens of thousands of kilometers. In large eruptions, the pyroclasts can cross into the stratosphere and spread around the world, in some cases altering climate. The eruption of Tambora in Indonesia is thought to be the cause of the 1816 “year without a summer.” The sulfur aerosols that Tambora emitted were dispersed throughout the northern stratosphere, causing decreased temperatures in North America and Europe that resulted in crop failure, starvation, and the deaths of thousands of people from extreme cold. Pyroclastic flows are also common in stratovolcanic eruptions, consisting of hot gases mixed with tephra that reach speeds of hundreds of kilometers per hour, destroying everything in their path. In addition, the eruptions can spread pumice and ash over the volcano’s slopes that can then be re-mobilized by precipitation, producing destructive debris flows in the valleys around the volcano. Some of these debris flows are hot, a characteristic described in many traditional histories. Few people live near the tops of stratovolcanoes, but the effects of their eruptions are felt by those living at their bases and even tens to hundreds of kilometers away. The appearance and size of stratovolcanoes commonly gives them a prominent place in indigenous populations.

The most viscous and gas-rich magmas are rhyolites. In some cases, the viscosity leads to very slow ascent rates and the gas separates from the magma. The eventual eruption is then a very steep-sided plug, which commonly collapses, sending rock and hot gas laterally as a pyroclastic flow for 1–20 km (e.g., the 1902 eruption of Mont Pelée on the island of Martinique, where an estimated 30,000 people died). In other cases, enormous quantities of rhyolite build up in the shallow crust and erupt in huge explosions lasting days to even weeks, eventually producing hundreds to thousands of kilometers cubed of tephra that spreads for enormous distances (e.g., tephra from the Long Valley eruption in California is 10 cm deep in Kansas, and tephra from the Campi Flegrei eruption in southern Italy is 10 cm deep near Moscow). These eruptions can alter the Earth’s climate for many years and devastate enormous areas. These are rare events—none has occurred during written history, although several

may have affected human development. The eruption of Campi Flegrei around 40,000 years ago may have affected modern human/Neanderthal interactions, and human migration into South-east Asia may have been slowed by the eruption of Toba around 80,000 years ago. The volcanoes that produce these eruptions are large and commonly form basins 5–50 km across, so large populations may live inside the volcano itself. The abundant signs of heat in these areas, such as fumaroles and hot springs, become part of the cultural understanding of nature.

It is surprising to note that despite their reputation, volcanic eruptions are not the great killers they are popularly thought to be. Estimates of volcano-related deaths over the past 100 years or so range from around 80,000 to just over 100,000, or 800–1,000 deaths per year, with only ten eruptions accounting for 80 percent of these fatalities. In contrast, a single earthquake has killed hundreds of thousands of people in a few minutes (Earthquake Statistics—USGS Earthquake Hazards Program <https://earthquake.usgs.gov/earthquakes/browse/stats.php>, accessed November 23, 2017).

Archaeological volcanology in practice

Archaeological volcanology is not a new field—much of the literate world is probably aware of the 79 CE eruption of Vesuvius and the archaeological excavations at the sites of Pompeii and Herculaneum—but it is one that has been transformed since the 1980s. The history of the field can be traced back to sociologist Gilbert White (1945), who was one of the first social scientists to investigate flood disasters and their impact on affected populations. Disaster studies became a primary focus of sociology by the 1970s, with anthropology following several years later (e.g., Hoffman and Oliver-Smith 2002; Oliver-Smith and Hoffman 1999). It was not until 1980, however, with the publication by Payson Sheets of *Archaeological Studies of Disaster, Their Range and Values*, that the roots of archaeological volcanology can be found. Since that time, the pace of research has accelerated as archaeologists and volcanologists began to see the importance of volcanic eruptions and the implications of this research for modern society. The history

of this research has been discussed in several publications and Cooper and Sheets (2012) and Grattan and Torrence (2007) should be consulted for more detailed information.

A wide variety of scientific tools have been used to investigate volcanoes and more tools are now being put into practice as technology becomes increasingly refined. Dating of eruptions is perhaps the most critical area, because human behavior is difficult to positively correlate with an eruption unless accurate dates are recovered. In general, the temporal placement of archaeological sites is easier and more accurate than the associated volcanic eruption, and more recent eruptions are easier to date than older ones. Dendrochronology has played a role in dating volcanoes since the late 1950s. In recent years, tree-ring research has become much more refined and dendrochemistry, which measures volcano-related elemental concentrations in dated tree-ring samples (Pearson et al. 2005), has been undertaken using laser ablation–inductively coupled plasma mass spectrometry (LA–ICPMS), X-ray fluorescence (XRF), and the ratio of strontium (Sr) isotopes. Other methods used to date eruptions include paleomagnetism (similar to archaeomagnetism and used to date lava flows), thermoluminescence, and radiocarbon, potassium–argon, argon–argon, and other forms of elemental decay dating. Archaeological association has been used for years to date eruptions and can be very accurate if dateable artifacts are found within the lava. The use of traditional cultural histories to provide relative (and sometimes very accurate) dates for eruptions is also becoming common, in contrast to earlier research that discarded this information as myth and therefore unreliable. Tephra studies (see *TEPHRA AND VOLCANIC ASH ANALYSIS*), particularly of stratigraphically deposited cinders, have also become common, and tephra is being used for relative dating and, through chemical analysis, to connect tephra to a specific eruption. The type and shape of tephra can also separate primary volcanic deposits from secondary (or redeposited) volcanic deposits, providing insight into the nature of the eruption impact. Isopach mapping of lava distribution and tephra depth can also distinguish areas that were permanently abandoned from areas that may have been abandoned temporarily but were later reoccupied.

From a theoretical perspective, archaeological volcanologists have used both traditional anthropological and archaeological models, as well as borrowed the concepts of “vulnerability” and “resilience” from sociology. Several well-known “disaster scales” have also been published over the years, which list variables that structure both the volcanic eruption and the human response, as well as the psychological impact of volcanoes on affected populations (Bawden and Reycraft 2000). It is anticipated that as archaeological volcanology matures, theory specific to the discipline will be further developed.

Future directions

Archaeological volcanology is a multidisciplinary field that has since the 1980s moved from an interest area for a few archaeologists and volcanologists to a legitimate scientific discipline with a dedicated body of practitioners. The goals of archaeological volcanology research are twofold: (1) to interpret, through the use of archaeological and volcanological methods and theory, the specific eruption and adaptive human behavior that are under investigation; and (2) to provide information to modern hazard and disaster researchers that can help with the planning and management of future disasters. At present, more archaeologists are involved in the field than volcanologists, but that is starting to change as word spreads to volcanologists and as more money is earmarked for disaster research.

Archaeological investigation fits well with this research due to its time depth, its behavioral focus, and its long-standing familiarity with and use of environmental variables. The emphasis by volcanologists on the details of the timing and processes of the eruption complements archaeological goals. Insights derived from archaeological volcanology investigations are now starting to be used by those in the hazards and disaster communities and should continue to increase in the future.

Around 50 volcanoes erupt worldwide every year and almost 1 percent of the world’s population, or around 500 million people, live in areas with active volcanism. Although the occupation

of these areas is partly due to their fertile agricultural soils, it is also a result of population growth, as more people are forced to settle in volcano- and disaster-prone areas. This in and of itself supports the importance of archaeological volcanology as a distinct scientific discipline, serving both as an avenue for research to better understand volcanic eruptions and human behavior, and as a resource that can be used to assist modern hazard managers and disaster planners.

Archaeoseismology

MANUEL SINTUBIN

KU Leuven, Belgium

Archaeoseismology is the study of earthquakes using evidence in the archaeological record. It is one of the disciplines that belong to the broad research field of earthquake sciences, which all share a common goal, that is, to reconstruct the earthquake history within a region with the purpose of assessing the seismic hazard and mitigating the seismic risk. The archaeological evidence for earthquakes comprises chaotic destruction layers, typical damage typologies to manmade constructions, displaced manmade constructions, indications of repairs, sudden abandonment of sites, sudden cultural changes, and so on.

Historically, earthquakes were used in the first half of the twentieth century by archaeological excavators to explain what otherwise could not be explained, at archaeological sites in earthquake-prone regions, such as the Mediterranean. Noteworthy in this respect was Sir Arthur Evans, the famous excavator of the Bronze Age Minoan site of Knossos on the island of Crete (Greece) in the eastern Mediterranean Sea. He was the first to consider earthquakes as the primary destructive agent, leaving clear marker horizons in the archaeological stratigraphy. The early development of archaeoseismology was subsequently grafted on archaeological work in the Mediterranean and Middle East, strongly dependent on identifying structural damage features to monumental buildings at archaeological sites (Stiros and Jones 1996). Earthquakes quickly turned out, though, to be used too easily as a “*deus ex machina*,” provoking skepticism within the community of earthquake scientists, who questioned whether cultural material data could reliably serve as earthquake indicators at all.

The primary challenge of the earthquake sciences is to better constrain the earthquake hazard which a community is faced with today and will

be confronted with in the future. Knowing the earthquake hazard, a community can take the necessary measures to mitigate the earthquake risk—that is, avoiding casualties and limiting damage to housing and infrastructure. The earthquake hazard is expressed as a probability that an earthquake of a certain magnitude or greater may occur, or that a certain level of ground motion may be exceeded, in a well-defined time period. Classically, a 10 percent probability in 50 years infers that the event considered has a return period of 475 years. This practice of probabilistic seismic hazard assessment (PSHA) is primarily based on the principle of elastic rebound. Over long periods of time, tectonic stresses build up in faults to a point that the friction on the fault is exceeded and the fault is activated, suddenly releasing the stored elastic energy, which radiates from the seismic source, causing an earthquake. This characteristic succession of interseismic periods of stress build-up and sudden events of coseismic stress release is known as the earthquake cycle. Another characteristic of active fault systems is a specific correlation between the magnitude of an earthquake and its frequency of occurrence, known as the Gutenberg–Richter distribution. Earthquakes with small magnitudes are rather common, and thus have a short earthquake cycle (months to years), while earthquakes with large magnitudes are rather rare, having a long earthquake cycle (centuries to millennia). To assess future seismic hazard, a reliable estimate of the parameters controlling the Gutenberg–Richter distribution (e.g., *b*-value) is a prerequisite. This can only be achieved by reconstructing the earthquake history in a region in as much detail and as far back in time as possible. However, seismic-hazard practitioners are confronted with the problem that the time window of instrumentally recorded earthquakes is too short; it only spans somewhat over a century. A magnitude–frequency correlation, solely based on a century of instrumental earthquake data, shows in most cases a margin of error, which is too wide to enable a reliable seismic hazard assessment. The archive of earthquakes therefore needs to be extended back in time, calling

upon all possible evidence for pre-instrumental earthquakes. On the one hand, information on pre-instrumental earthquakes can be found in all types of historical—written—records (historical seismology). On the other hand, paleo-earthquakes leave their marks in the geological and/or geomorphological record (paleoseismology and earthquake geology). In this broad research field of earthquake sciences, reflecting a continuum of overlapping and complementary disciplines, archaeoseismology, focusing on cultural material data spanning the last few millennia, occupies a unique position, bridging the gap between instrumental and historical seismology on the one side, and paleoseismology and earthquake geology on the other. Depending on the time span of occupancy, possibly expanding over one or more earthquake cycles, archaeological sites can provide crucial information to seismic-hazard practitioners.

Another issue seismic-hazard practitioners are confronted with is the nature of the pre-instrumental earthquake evidence. From their perspective, it is imperative to know the physical parameters of each earthquake, brought together in an earthquake catalogue. These parameters include the date of the earthquake, its magnitude, its seismic source, its epicenter, the duration, and the ground acceleration. All these parameters can be instrumentally measured, and are thus known for most of the instrumentally recorded earthquakes. However, pre-instrumental earthquakes can only be parameterized indirectly, based on the evidence found in the historical, archaeological, and/or geological record. This indirect evidence can be split into two categories. On the one hand, there is primary evidence, directly related to coseismic surface rupturing or ground failure. On the other hand, there is secondary evidence, related to coseismic ground shaking and ground motion. The challenge is to translate this indirect earthquake evidence into (semi-) quantitative parameters that can be used in a seismic hazard assessment.

In archaeological contexts, earthquake archaeological effects (EAEs) can also be classified into primary and secondary evidence. Moreover, a third category of earthquake evidence can be distinguished in archaeological and historical contexts—that is, the postseismic, delayed-response effects of an earthquake, such

as fire damage, repairs, recycling of building materials, complete or partial abandonment, and architectural and/or cultural changes.

Two types of primary or secondary EAEs can furthermore be distinguished: structural effects on manmade constructions and stratigraphical effects in the archaeological stratigraphy. While the former effects received the most attention in the development of the discipline, focusing on archaeological contexts with monumental constructions, the latter effects have attracted more interest recently, in particular when focusing on archaeological contexts dominated by rubble architecture.

The most obvious primary structural EAEs are archaeological remains that are displaced due to the coseismic surface rupturing on an active fault. These faulted relics not only enable the identification of active faults in the landscape, but also allow the determination of the type of faulting, the amount of coseismic slip related to a single earthquake, as well as the cumulative fault slip caused by multiple earthquakes during the existence of the displaced manmade construction; knowing the age of construction, a time-averaged fault-slip rate spanning centuries to millennia can be derived. In this respect, the study of faulted relics is very comparable to paleoseismological work. These fault-slip rates obtained from an archaeological context can be compared with slip rates, obtained from paleoseismological and geological contexts on the same active fault. Such comparison may reveal potential slip deficits, inferring a high seismic hazard.

Secondary structural EAEs, caused by coseismic ground shaking and ground motion, comprise typical strain structures in the building fabric. These earthquake-related damage features are most obvious on monumental buildings and constructions. Recognizing such structural damage features in rubble architecture, on the other hand, is a challenge. Coseismic ground shaking can generate a wide range of typical damage features, such as penetrative fractures in masonry walls, rotated and displaced drums in columns, dropped keystones in arches, collapsed stairways, domino-type collapsed walls and columns, and U-shaped gaps in walls. Coseismic ground motion, for example, due to liquefaction, can generate other types of damage features, such as folded and fractured pavements, and

tilted, rotated, and bent walls. All these structural EAEs are assessed semiquantitatively by using modern earthquake intensity scales, which are applied in assessing the earthquake damage caused by recent—and thus instrumentally recorded—earthquakes (e.g., the European macroseismic scale EMS-98). An additional challenge is to unambiguously distinguish damage caused by an earthquake and damage caused by other destructive agents, such as natural failure, storm, vandalism, looting, or warfare. Moreover, it is very difficult to attribute specific damage features to a single earthquake, in particular in earthquake-prone regions, where ancient buildings at archaeological sites have most probably experienced ground shaking from numerous earthquakes over their lifespan and even following final abandonment. The danger thus exists that by attributing damage features that may have been caused by a whole series of earthquakes to a single earthquake, unrealistic earthquake catastrophes emerge, which subsequently may find their way into earthquake catalogues.

The stratigraphical effects of earthquakes is materialized in archaeological destruction layers or deposits, defined as horizons showing evidence of sudden destruction caused by human and/or natural agents, commonly covering a “living surface,” evidenced by, for example, in situ broken vases, buried valuable objects, and/or skeletons of victims. Earthquake-related destruction deposits further contain burned material, charcoal, collapsed architectural debris, and crushed and toppled objects. In archaeological contexts, lacking any structural EAEs, destruction layers may provide the only evidence for ancient earthquakes. Again, relating a destruction horizon to an earthquake is rarely unambiguous and remains a challenge for archaeoseismology. The principal issue with the study of destruction layers concerns the preservation and disturbance of destruction layers. Earthquake debris may have been cleared from streets and buildings and disposed of at particular dumpsites, so that no destruction layer is preserved in the archaeological stratigraphy. Valuables and/or victims may also have been recovered from the debris, while material may have been recycled in rebuilding efforts, resulting in very disturbed destruction horizons. The preservation of pristine destruction layers may therefore depend more on social

factors, such as the degree to which the affected community was able to cope with the aftermath of the earthquake, than on physical parameters, such as the magnitude and proximity of the earthquake. This results in a very incomplete stratigraphical record of earthquakes, which is moreover not evenly distributed through time. This preservation issue concerns not only stratigraphical earthquake evidence but also structural earthquake evidence, resulting in an observation bias in archaeoseismology, focusing on periods of upheaval, destruction, abandonment, and so on.

Constraining the timing of the damaging earthquakes is one of the greatest challenges in archaeoseismology. Chronological control is achieved by bracketing earthquake evidence with a minimum (*terminus ante quem*) and maximum (*terminus post quem*) age. Alongside radiometric dating methods (e.g., radiocarbon dating), archaeological dating tools, based on, for example, architectural styles, ceramic style changes, coins, and inscriptions, are used in constraining the timing of earthquakes. The accuracy and precision of the age control largely depends on the type of dating applied and on whether or not multiple age determinations, using complementary dating methods, have been performed. The main issue with respect to archaeological earthquake evidence is rather poor temporal resolution, ranging from decennia to centuries, making it nearly impossible to pinpoint archaeological earthquake evidence to historical earthquakes. The danger, moreover, exists that ancient earthquakes, poorly constrained in time, are equated with historically documented earthquakes, based on an inherently incomplete earthquake catalogue. When, subsequently, the archaeological earthquake evidence is used as supplementary proof for the historical earthquake, a circular argument arises. Poor temporal resolution may also lead to erroneous interpretations of earthquake evidence as the result of a single oversized earthquake, on the one hand, the sequence of the main shock and its aftershocks, and on the other hand, a clustered series of earthquakes. Finally, poor age constraints hamper the territorial correlation of EAEs between different archaeological sites, again giving rise to the danger of amalgamating earthquake evidence for regionally distinct earthquakes into a single catastrophic earthquake. This problem of regionally

correlating archaeological earthquake evidence also limits our ability to quantitatively assess the physical parameters of ancient earthquakes.

Indeed, the magnitude of a pre-instrumental earthquake is assessed semiquantitatively based on the spatial distribution of secondary earthquake evidence, reflecting variable ground motion intensities away from the earthquake's epicenter. By comparing these earthquake intensity distribution maps of pre-instrumental earthquakes with intensity distribution maps of recent, instrumentally recorded, earthquakes in the same region, a reliable magnitude estimate of pre-instrumental earthquakes can be derived. In addition to the poor temporal resolution of archaeological earthquake evidence, hampering a valid regional correlation, the mapping of secondary archaeological earthquake evidence is strongly limited because archaeological sites are rather sparsely and unevenly distributed. Only in regions with a long and rich archaeological heritage does such regional mapping provide useful intensity distributions, which allow the magnitude of an ancient earthquake to be assessed. There is, though, a remarkable spatial bias that can be advantageous for archaeoseismological work. In earthquake-prone regions, human settlements are often located in the direct proximity of active earthquake faults, in what are called seismic landscapes, that is, landscapes resulting from the cumulative geomorphological effect of successive, surface-rupturing earthquakes. There is an increased likelihood of these archaeological sites having a record of both primary and secondary earthquake effects, caused by earthquake activity on the nearby fault. However, the dominant presence of nearby EAEs also obscures the possible presence of far-field EAEs, making regional correlations of EAEs much more difficult. On the other hand, the absence of EAEs at an archaeological site in a seismic landscape may reveal that the faults in the direct proximity of the site were not active during the occupancy of the settlement.

Before a magnitude can even be derived for an ancient earthquake, archaeoseismology is thus still confronted with a number of challenges. To address these challenges, modern archaeoseismology aims to integrate the principles and practices of a very wide range of sciences, from

geophysics to structural engineering. Such a multidisciplinary approach requires a shared protocol and a standardized methodology (see Sintubin and Stewart 2008 and references therein). In recent years, a clear shift towards more quantitative and multidisciplinary approaches has definitively boosted the use of archaeoseismological evidence in seismic-hazard studies. Quantitative archaeoseismology (Hinzen et al. 2010) focuses on, for example, a forward modeling approach, based on earthquake engineering models applied to ancient manmade structures. Scenario-based earthquake ground motion simulations test realistic earthquake hypotheses to explain structural EAEs in ancient buildings. Such a modeling approach is helped by modern visualization techniques, such as 3D laser scanning (see AIRBORNE LASER SCANNING AND LIDAR), which allow the creation of a quantitative, high-resolution, three-dimensional structural model of the ancient building. Quantitative archaeoseismology not only assesses archaeological earthquake evidence with respect to ground motion parameters and magnitude estimates of ancient earthquakes, but also unambiguously discriminates between damage caused by earthquakes and damage caused by other natural or anthropogenic agents. While this quantitative archaeoseismological practice is very effective on sites with monumental architecture, a more semiquantitative, multidisciplinary territorial approach is more appropriate in archaeological contexts dominated by rubble architecture and associated destruction horizons (Jusseret and Sintubin 2013). This approach starts from the seismotectonic context of the archaeological site, identifying the different types of potential seismic sources, as well as their empirical ground-motion relationships. From an archaeological perspective, a well-documented, high-visibility archaeological context, characterized by distinctive and rapid ceramic changes, which provide a good chronological framework, is required. Subsequently, different earthquake hypotheses are tested in an iterative process, eventually leading to an earthquake scenario that provides the best explanation for the EAEs observed in the archaeological context studied.

Finally, by highlighting how communities in ancient times coped with earthquakes, archaeoseismology can boost earthquake awareness in

present-day communities living near archaeological sites bearing evidence of ancient earthquakes. In this respect, archaeoseismology can be part of public policy to mitigate earthquake risk.

Barley, Rye, and Oats

MERIEL MCCLATCHIE

University College Dublin, Republic of Ireland

Barley

Barley (*Hordeum vulgare* L.) is an important cereal that can thrive in a greater variety of conditions when compared with wheat, including drier and colder environments, poorer soils, and more saline sediments. It is this resilience that supported the spread of barley from the Near East—where it first began to be farmed—and its uptake in many other parts of the world. Barley grains were used in breads, vessel-based stews and gruels, alcoholic drinks, and fodder, while chaff and straw were used in objects and structures.

Domesticated barley (*Hordeum vulgare* subsp. *vulgare*) is among the first crops to be domesticated in the Near East—a founder crop (Zohary, Hopf and Weiss 2012; Fuller 2015). It is likely that barley was growing wild in southwestern to central Asia, as it does today, and these wild progenitors were domesticated. The wild ancestor of barley is thought to be *Hordeum vulgare* L. subsp. *spontaneum* (C. Koch), which can be found around the east-Mediterranean basin and west Asiatic countries. Genetic studies suggest there were several independent centers of domestication for barley, including the Fertile Crescent (a large area that encompasses Israel to western Iran) and further east within the Iranian plateau (Morrell and Clegg 2007).

Even before domestication, wild barley was gathered as a foodstuff (Zohary et al. 2012, 56), for example in Israel at Ohalo II (23,000 BP) and even earlier at Kebara Cave (50,000 BP). Pre-domestication cultivation occurs during the PPNA period (9700–8800 BCE)—a hoard of 260,000 wild barley grains was found at Gilgal, Israel. Over the course of the following 3,000 years, gradual change in the morphology of barley grains and chaff is observed, including

an increase in grain size and in the percentage of non-brittle rachis remains, reflecting domestication. Cultivated barley is recognized by its non-brittle ears, where the spikes remain intact after ripening, enabling harvesting by humans. By contrast, the ears of wild barley are brittle, and at maturity they disarticulate to self-disperse the grains and ensure survival of the plant. Disarticulation scars in wild, brittle forms are often smooth, while in domesticated varieties, threshing results in rough breakage scars.

Barley ears contain spikelets arranged in groups of three alternately along the rachis. The spikelets of domesticated barley are found in a two-rowed form (only the middle spikelet in each group of three is fertile and produces a grain; the two lateral spikelets are grainless) or a six-row form (all three spikelets on each side are fertile and grain-producing). The wild progenitor of barley is a two-rowed form. The six-rowed form evolved under domestication, arising from a genetic mutation that resulted in a failure of the central floret to suppress lateral florets. Wild barleys and many domesticated forms are hulled, where the grain is tightly enclosed by chaff. Naked barleys emerged slightly later, when a single recessive gene caused the hulled trait to disappear, which resulted in grains being looser in the spikelet and easier to process. Early examples of non-brittle, two-rowed barley that are clearly domesticated were found at Tell Aswad, Syria (late 9th/early 8th millennium BCE) and Jarmo, Iraq (later 8th millennium BCE), often as a companion of wheat (Zohary et al. 2012, 56–7). More advanced forms of barley, such as six-row hulled and naked, appear later, during the 8th/7th millennia BCE.

Widespread uptake of barley prompted its movement from southwestern and central Asia to the Aegean region, and subsequently to the Balkan countries, Caucasasia, the west Mediterranean basin and central Europe, western Europe, north Africa, the Indus Valley, and other regions (Zohary et al. 2012; Stika and Heiss 2013). From the 6th millennium BCE, Neolithic societies in

the Balkans, central and western Europe were cultivating barley, often six-rowed and naked forms. Barley reached the furthest margins of western Europe, such as Ireland, soon after 4,000 BCE. By the Bronze Age barley had become more important than wheat in several regions, particularly hulled barley. Barley also spread eastwards to the Indus Valley and Turkmenistan by 6,000 BCE. Barley cultivation in Egypt and along the Nile appears later, around 4,000 BCE. It was after 3,000 BCE that barley began to be cultivated in monsoonal India, and around 2,000 BCE in southern India and China.

Rye

Rye (*Secale* L.) is another cereal whose wild progenitors derive from the Near East, but rye has a very different evolutionary history (Zohary et al. 2012). Nowadays, rye is a staple crop in several regions. Rye flour is baked to produce a dark, dense bread or crispbread/crackers, the grains are used in high-energy animal feed and rye whiskey, the straw in structures and thatching, and the green plants provide early spring grazing. Rye is a relatively tolerant crop that can withstand poor and sandy soils, as well as cold and drought. Rye is unusual among cereals because it is cross-pollinated, which means that its yield is partly dependent on wind pollination, and it disperses pollen more freely than other cereals; for this reason, rye can be over-represented in pollen records (see PALYNOLOGY) when investigating Holocene vegetation change.

Four taxonomic groups of the rye genus have been identified (Zohary et al. 2012, 59–61). The best known is *Secale cereale* L., which contains the domesticated varieties of rye, as well as many weedy races and wild forms. Domesticated varieties are annual free-threshing, nonshattering plants with large, plump grains. Weedy forms of *Secale cereale* are also annuals, found growing slightly to the north of wild stands of barley and wheat, in western and central Asia, and south-east Europe. Other taxonomic groups belonging to rye are the perennial *Secale montanum* Guss. and two annuals, *Secale iranicum* Kobyl. and *Secale sylvestre* Host.

When compared with barley, rye is rather different in terms of its evolution and uptake (Behre 1992; Zohary et al. 2012, 62–5). Early examples of wild rye, presumably gathered, are recorded at Epipalaeolithic Tell Mureybit, Syria (10th millennium BCE). Domestication appears to have taken place in the area around Turkey and Armenia, possibly involving an annual brittle rye (*Secale cereale* subsp. *vavilovii*) or *Secale montanum* Guss., or both. Rye remains that suggest domestication are present at 8th/7th millennium BCE sites in Turkey, such as Can Hasan III and Çatalhöyük East; in the former, relatively plump grains were recorded, as well as nonshattering rachis remains. It is striking, however, that very few remains of gathered or domesticated rye are found in Neolithic and Bronze Age south-west Asia, even though wild forms of *Secale cereale* grow in this region.

Rye migrated to Europe during the Neolithic, perhaps via the Aegean basin and south Balkans, as suggested by finds in Italy and Slovakia, but did not yet become a staple crop. While rye has been found at several Neolithic and Bronze Age sites in central, eastern, and southern Europe, these finds reflect tolerated weeds of wheat and barley crops, rather than rye as a crop in its own right. It is not until the Iron Age–Roman period in Europe that rye appears more frequently and emerges as a staple crop (Behre 1992; Stika and Heiss 2013). Rye is particularly suited to northern Europe because of its winter hardiness, resistance to drought, and ability to thrive on acid, sandy soils. Rye became significantly more important during the early medieval and medieval periods, although historical sources indicate that ergot (*Claviceps purpurea*), a common fungal disease of rye, was a problem in medieval Europe. Rye continues to be grown in Europe and Russia today, as well as North Africa, the Americas, and South Africa. During the twentieth century, a new crop, *Triticale*, was developed by artificially crossing wheat with rye.

Oats

Common oat belongs to the *Avena* genus, which comprises around 25 annual species (Baum 1977; Zohary et al. 2012, 66–7). Several species of oat have been domesticated, but only

one species—*Avena sativa*, common oat—has prevailed as an important cereal. *Avena sativa* comprises many domesticated varieties, including *Avena sativa* in the narrow sense, *Avena byzantina* C. Koch and *Avena nuda* L. Other species, such as *Avena strigosa* Schreb. and *Avena abyssinica* Hochst., persist as minor crops around the world. Common oat is used in flat breads and biscuits, porridges, gruels, and many other vessel-based preparations, including alcoholic drinks.

Common oat shows close genetic affinities and morphological similarities to a variety of wild and weedy oats growing in the Mediterranean basin, including *Avena sterilis* L., *Avena ludoviciana* Dur., *Avena occidentalis* Dur. and *Avena fatua* L. (Zohary et al. 2012, 66–7). Even before its domestication, oat was gathered as a food. Grinding tools in Israel (23,000 BP) and Italy (32,600 BP) have produced evidence for starch grains (see STARCH GRANULE ANALYSIS) of wild oat on their surfaces, suggesting the tools were used to create oat flour. Pre-domestication cultivation has also been recorded at Gilgal, Israel (9th–8th millennia BCE), where a large assemblage of *Avena sterilis* (c.12,000 grains) was found.

It appears that domesticated *Avena sativa* is descended from *Avena sterilis*, but identification of when and where domestication occurred has proved challenging (Zohary et al. 2012; Stika and Heiss 2013; Fuller 2015, 547). Oat chaff—specifically the floret base—is required for secure identification, but the paleoethnobotanical record is often dominated by grains. Grain size is an indicator of domestication, as domesticated grains are usually larger than those of wild relatives, but less reliable than chaff. It is suspected that oat was first domesticated in Europe. Oat is a “trans-domesticate,” whereby its wild ancestral distribution is distinct from the location of domestication. Oat was transported from wild stands, most likely in the eastern Mediterranean region, through human action, moving as a weed of wheat and barley. Oat migrated through Europe during the Neolithic as a backpacker on the actual crops of wheat and barley, and it was not until much later, during the Later Bronze Age and Iron Age, that oat was domesticated. When compared with wheat and barley, oat is well suited to wetter and colder environments, and the presence of these conditions in central and western Europe

enabled oat to thrive. Perhaps on occasions when wheat and barley crops failed, oat began to be harvested as an “emergency” crop, and eventually cultivated as a crop in its own right. Alternatively, oat may have displaced the main crops of wheat and barley where ecological conditions were more suited to oat, and then been taken into cultivation.

Oat is recorded in Neolithic and earlier Bronze Age deposits in Europe, usually in small quantities, but these records are thought to reflect a wild variety. Firm evidence for domesticated oat is found first in Europe, from the 2nd and 1st millennia BCE, for example at a Later Bronze Age granary in Langweiler, Germany. Roman agricultural writers seldom mentioned oat, and where mentioned, it was referred to as a food crop for horses (Ruas and Zech-Matterne 2012). It is not until the early medieval period that oat becomes an important crop in several parts of Europe. This continued to be the case during the medieval period, with oat reaching North America in the seventeenth century.

Beverages

MATTHEW E. BIWER

University of California, Santa Barbara, USA

Beverages, defined here as any type of liquid substance consumed by ancient peoples, are recognized by archaeologists to have occupied important social, political, economic, and religious functions within ancient societies. As food, beverages not only nourish, but can also be used as payment, social lubrication, as a marker of social categories, as a means of preserving food, an important part of ritual activities, or may contain medicine to heal or induce an altered state of consciousness. Beverages are also difficult to recover from archaeological contexts due to the physical nature of liquids. However, evidence for beverages can take several forms reflecting different aspects of human activity, including: organic residues from preparation or consumption, plant remains, historic documents, and ethnographic evidence. Archaeologists collaborate with colleagues in a wide range of disciplines to investigate the production, storage, serving, and consumption of beverages that preserve in the archaeological record. Common analytical methods employed in these investigations include biochemical and paleoethnobotanical analyses.

The use of biochemical analysis has become more widespread in archaeology in recent decades, focusing on plant and animal food residues and chemicals that were absorbed within ceramic vessel walls, including lipids, amino acids, resins, and other organic residues (see ORGANIC RESIDUE ANALYSIS). Two common methods of chemical analysis of beverages within archaeology include high performance liquid chromatography (HPLC) and gas chromatography (GC), which may be used in combination with mass spectrometry (MS) to identify and analyze residues of beverages left behind on ceramic vessels or other artifacts. Combining these two complementary chromatographic techniques with mass spectrometry, archaeologists

are able to separate a sample of organic residue into its individual components, which are then examined for biomarkers of past human activities. For example, liquid chromatography mass spectrometry (LC-MS) has been used to detect compounds associated with Black Drink, a ritual purgative beverage made from parched *Ilex vomitoria* (Yaupon holly) leaves and twigs that are boiled in a pot with water. Indeed, ursolic acid and residues of methylxanthines theobromine and caffeine, considered to be biomarkers for *Ilex vomitoria* plants used in the creation of the ritual Black Drink, were found on ceramic beakers from the Mississippian site of Cahokia near modern day St. Louis, Missouri (Crown et al. 2012). The authors argue that the unique combination of ursolic acid, theobromine, and caffeine, indicates that Black Drink was present in the sampled ceramics.

Cacao (*Theobroma cacao*) was a key ingredient in a variety of ancient beverages, and its detection is of particular interest to archaeologists trained in biochemical methods. Using the fruit of cacao tree that grows in the Mesoamerican tropics, cacao beverages are brewed by fermenting the pulp around the seeds in the pod, drying and toasting the seeds, and then grinding the seeds to add to cold water, possibly with other ingredients including ground maize (*Zea mays*) and chili peppers (*Capsicum annuum*) to create a variety of beverages. The seeds used to make cacao beverages, consumed mainly by elites in ancient times, were widely traded throughout Mesoamerica and were introduced into the American southwest around AD 1000–1125 (Crown and Hurst 2009). Using HPLC coupled MS, the authors identified theobromine, caffeine, and theophylline—three biomarkers that infer the presence of cacao—from dry residues on ceramic cylindrical jar fragments recovered from trash middens near Pueblo Bonito in Chaco Canyon, New Mexico. The presence of cacao residues in these cylinder jars is the first evidence for the trade of the seeds north of Mexico and may indicate that cacao beverages similar to the ones prepared in Mesoamerica were being used in ritual activities in Chaco Canyon.

Archaeologists trained in biochemical techniques have also studied ancient viticulture (see GRAPES AND VITICULTURE). For example, terebinth (*Pistacia* sp.) resin and tartaric acid have been identified as biomarkers of wine in amphora dating to 500–475 BC in the Mediterranean. Indeed, these studies have not only confirmed that wine was stored in recovered amphorae due to the presence of tartaric acid in the samples, but also provide insight into the ways in which wines were shipped, stored, and used. Compounds detected in imported Etruscan amphorae from central Italy excavated in the southern port city of Lattara in France suggest that herbs, including rosemary (*Rosmarinus officinalis*), basil (*Ocimum basilicum*), and thyme (*Thymus vulgaris*), were added to the grape wine, indicating a possible medicinal role for wine during this period (McGovern et al. 2013). Additionally, compounds from pine (Pinaceae) resin were also recovered from the amphorae, shedding light on preservatives added to the wines for shipping. This particular biochemical study not only illustrates techniques for Etruscan winemaking and trade, but also provides some of the earliest evidence for the importation of wine into France, which is crucial for characterizing the early history of viticulture in this part of the Mediterranean.

The analysis of paleoethnobotanical remains represents another useful method for investigating beverages produced and used in the past. Two forms of paleoethnobotanical remains are available for analysis: macrobotanical (seeds, wood charcoal) and microbotanical (pollen, starch grains, phytoliths). Macrobotanical remains have provided physical evidence for the production of beverages through physical changes in seeds. One way the physical form of the seed may be altered is through the process of malting, which involves soaking and sprouting grain in water to convert starches within the seeds into sugars for fermentation into alcohol (ethanol). Bouby, Boissinot, and Marival (2011) provide paleoethnobotanical evidence for malting at the fifth century AD Roquepertuse (Velaux) site in southeastern France where they recovered a high density of barley (*Hordeum vulgare*) in a state of induced germination. Considering this evidence in combination with the presence

of grinding equipment, ovens, and fermentation pots at the site, the authors suggest that the context represents household-level beer production. Another study demonstrated that wine was produced in Roman southern France at the site of Gasquino, evidenced by crushed grape skins, pedicels (stems), *Vitis* sp. wood charcoal, thousands of pits linked to wine production in fields surrounding the site, and large ceramic containers (dolias) suitable for storing wine that were sunk into the ground. Using multivariate statistics, the researchers found that both wild (*Vitis vinifera* subsp. *sylvestris*) and domesticated (*Vitis vinifera* subsp. *vinifera*) grape varieties were used in local viticulture (Figueiral et al. 2010), providing evidence for the spread and cultivation of grapes throughout the region since the fourth century BC. Archaeologists have also documented that the shape of drupes (fruit seeds) from the molle (*Schinus molle*) tree change from spherical to irregular and lobed when either soaked in water or boiled to extract sugars and flavors for the production of *chicha de molle* (a type of Andean beer). Molle drupes that were either soaked, boiled, or both have been recovered from a brewery located at the Wari regional imperial center of Cerro Baúl in Moquegua, Peru; these data provide evidence for the processing, boiling, and fermenting of *chicha*.

Microbotanical remains are also useful for the study of ancient beverages, especially in contexts where preservation of macrobotanical remains is limited. Using a high-powered polarizing stereoscope or scanning electron microscope, paleoethnobotanists can identify pollen (see PALYNOLOGY), phytoliths (see PHYTOLITH ANALYSIS), and starch grains (see STARCH GRANULE ANALYSIS). In the Andean highlands of the Lake Titicaca basin, maize phytoliths have been used to both track the spread of domesticated maize into the Andes and determine that the probable first uses for maize in the area included the production of *chicha* for ritual purposes around 800–250 BC (Logan et al. 2012). When compared to the abundance of maize phytoliths on grinding stones near ritual spaces, incense burners, and the teeth of sacrificial victims, a lack of maize phytoliths in household cooking vessels suggests maize was first used for ritual purposes rather than for daily household consumption. Additionally, a study

of phytoliths and residues recovered from vessels from Oaxaca, Mexico dating to the seventh century AD documented the presence of maize and theobromine, suggesting that a culturally important beverage in contemporary Mesoamerica (*tajete*, made from cacao seeds and ground maize) may already have a long history of production and storage (Soleri et al. 2013). While the presence of theobromine residues and maize phytoliths in these vessels is not definitive proof that *tajete* was produced during this period, it nevertheless provides a starting point for revealing the recipes of ancient beverages. Further study of the material culture, ethnohistoric literature, and plant remains at this site may yet provide additional evidence for the production of the *tajete*. Finally, pollen recovered from Coptic amphorae from the early medieval period (fourth to seventh centuries AD) site Šarun in Middle Egypt was found to derive from grapes, suggesting wine was stored in these amphorae (Rösch 2005). Some of the samples may have been sweetened with honey, inferred from the presence of pollen from insect pollinated species. The same study found insect pollinated pollen types were present in a mortuary bowl excavated at the late Hallstatt period (800 to 480 BC) site of Niedererlbach in Bavaria, indicating this bowl once contained mead.

While each of these approaches provides supporting evidence that beverages were produced, stored, or consumed in particular archaeological contexts, finding definitive proof for the presence of a specific beverage, or its individual constituents, is difficult. Incorporating multiple lines of evidence, an interdisciplinary approach considering paleoethnobotanical remains, chemical residues, with other artifacts, architectural space, and ethnographic and ethnohistoric materials, provides the best course for investigating and interpreting the production, consumption, and uses of beverages in the past. Additionally, the archaeological study of beverages has not only helped identify the presence of drinks in the past, but it has also contributed to our understanding of their broader political, social, economic, and religious significances. Archaeological studies of beverages can be used to investigate human activities, such as labor, trade, architecture, domestication, medicine, the arts, human diet, and evolutionary biology. Future studies of beverages in archaeology, incorporating multiple

scientific and historical approaches, could contribute an enhanced characterization of beverages in the past, insights into flavors and culinary experiences, and a fuller understanding of our cultural and biological past.

Biogeography

NAOMI SYKES

University of Exeter, UK

With the rise of global trade, plants and animals have found it increasingly easy to move beyond their natural range and, since the early 1800s, the number of “alien species” has risen sharply, with hundreds of exotic plants and animals becoming established worldwide. However, people have purposefully and inadvertently translocated animals and plants for millennia (O'Connor and Sykes 2010; Prance and Nesbitt 2012). Indeed, it is now widely recognized that archaeological studies of plant and animal biogeography can be undertaken as proxy measures of past human migration and colonization (see ZOOARCHAEOLOGY AND HUMAN TRADE AND MIGRATION). Many studies have examined the spread of farming during the Neolithic period (see DOMESTICATION), but biogeographical analysis has the potential to answer a wider suite of questions concerning environmental and cultural change, as well as providing data of relevance to present-day biodiversity management.

In order to gain the above information, and map ancient distributions of plants and animals, identification of archaeological material to species is a necessity. Unfortunately, species differentiation is not always straightforward, especially for closely related taxa (e.g., wild and domestic varieties), and often requires verification by detailed morphological studies, such as geometric morphometrics (see GEOMETRIC MORPHOMETRICS) or genetic analyses (see GENETICS: ANCIENT). Even where identifications are secure, it is important to remember that the bioarchaeological record is the result of human activity and cultural choices. If species are absent from archaeological assemblages, or present only in low frequencies, it does not necessarily mean that they were absent in the surrounding landscape; they may simply not have been exploited by people. Conversely, some species may be

represented archaeologically in areas where they were not present in life, especially if their parts were curated and transported to regions beyond their natural range. For instance, there is debate concerning whether fruit stones found in archaeological deposits represent imported dried fruits or those that were locally grown (see FRUITS, VEGETABLES, AND NUTS). Similarly, animal body parts, for example, skins, antlers, horns, and tusks, were frequently traded as raw materials, medicines, or curios, and, as such, do not reflect the presence of established animal populations.

While trade in plant and animal products is interesting in its own right, it obscures our understanding of ancient biogeographies. Patterns can also be confused by intrusive specimens that have worked their way through the stratigraphy to become incorporated in earlier deposits. Radiocarbon dating of key materials is, therefore, vital to validate interpretations. Other forms of isotope analysis may then help to clarify whether plants and animals were locally raised or imported (see MOBILITY AND OXYGEN ISOTOPES and MOBILITY AND STRONTIUM ISOTOPES). One example where radiocarbon dating and isotope analyses have been combined successfully is with regard to the introduction of the Mediterranean fallow deer (*Dama dama*) to Britain, the timing of which has long been debated. Several Roman sites in southern England have yielded fallow deer remains, and a recent program of ¹⁴C dating indicated that many (but not all) were indeed Roman, dating between the first and fourth century CE (Sykes 2014, 94). By undertaking multi-isotope analyses of these Roman specimens it was possible to demonstrate that the later-dated animals were born and raised in Britain (indicating established breeding populations), but also to identify a first-century first-generation import (see ZOOARCHAEOLOGY AND STABLE ISOTOPES). From where this imported individual derived was hinted at by the DNA analyses of these specimens whose genetics are most consistent with modern Italian fallow deer (Sykes 2014, 94).

DOI: 10.1002/9781119188230.saseas0062

In the case of the fallow deer, it would seem that the widely held assumption that introduced plants and animals were brought by “invading peoples” (here, “the Romans”) was correct. More often, however, the driver for biota diffusion was trade rather than conquest. For example, the numbers of faunal species introduced to Britain are high in periods when the island was well connected to mainland Europe (Neolithic, Bronze Age, Late Iron Age/Roman, and later medieval), but low when trade contacts were poor (Iron Age and Anglo-Saxon). The archaeobotanical record for Britain demonstrates almost identical trends (Sykes 2014, 79).

The arrival of new plants and animals is often interpreted in economic or dietary terms, but it seems that many introduced species were not initially exploited for food; instead they were incorporated into religious practices, often associated with specific deities. In Europe, for instance, the spread of the horse (*Equus caballus*) was mirrored by that of a human–equine divinity, common, albeit in different guises, across Indo-Europe; the brown hare (*Lepus europaeus*) was associated with a less well-known female deity that may (or may not) have evolved into the Anglo-Saxon goddess Eostre, from which Easter takes its name; and fallow deer were associated with the goddesses Diana and Artemis, and the chicken (*Gallus gallus*) with the Roman messenger god Mercury (Sykes 2014, 96–98).

The chicken’s association with the god of travel is particularly apposite, since this species is now the most widespread livestock animal on the planet: a perfect biogeographical case study of human-assisted transportation. As such, the chicken has become the focus of international research as archaeological scientists seek to determine the timing and circumstances by which this culturally and economically important bird spread around the world from its homeland in Southeast Asia. Scientific datasets for different geographical regions are highly uneven, which has resulted in a patchy understanding of the chicken’s diffusion. A synthesis of the available zooarchaeological and dating evidence is presented in Figure 1.

There have been several high-profile studies of the chicken’s eastward spread from Southeast Asia, through Oceania and to the Americas (see

Thomson et al. 2014). These have consisted predominantly of genetic analyses, few of which have given consideration to the cultural, zooarchaeological, or radiocarbon evidence (although see Matisoo-Smith 2015). Generally, all these studies agree that chickens were gradually hopped across the islands of the Pacific during the third and second millennium BCE, taken by people of the maritime Lapita culture who colonized both Near and Remote Oceania (see Matisoo-Smith 2015). The chicken’s arrival in South America was thousands of years later, the earliest radiocarbon-dated evidence suggesting establishment by the fourteenth or fifteenth century CE (Matisoo-Smith 2015, 98). Whether these chickens were brought from Polynesia by the Lapita culture or from Europe by early explorers of the Americas is a more contentious issue, as competing genomic laboratories have generated contradictory aDNA results (see Thomson et al. 2014; Matisoo-Smith 2015). The polemics surrounding these results serves as a reminder that genetic analysis is far from infallible and that interpretations drawn from the data are just that—interpretations—which are strongest when integrated and contextualized with other independent lines of evidence. Genetics alone is not enough (see ZOOARCHAEOLOGY AND ANCIENT DNA).

Until recently, the chicken’s eastward diffusion has attracted little attention, so there are currently few ancient DNA studies or radiocarbon-dated specimens, aside from those presented in Flink et al. (2014): this paper in particular highlights the problems of bioturbation and intrusion in the archaeological record, as one purportedly “Iron Age” specimen returned a modern genetic signature and then, unsurprisingly, a modern ^{14}C date. While the timing of the chicken’s eastward spread is not known precisely, zooarchaeological and cultural data are available, allowing introduction date and fluctuations in population and significance to be estimated (Figure 1). These data are most numerous for Europe, but other regions are beginning to generate important results.

For Africa and the Near/Middle East, two site-specific studies (Perry-Gal et al. 2015; Woldekiros and D’Andrea 2016) have combined radiocarbon-dated zooarchaeological evidence with broader cultural analyses. Through this integrated approach, they have presented compelling hypotheses concerning the timing and

Figure 1 Diffusion of domestic chickens from Southeast Asia. Top: A, earliest domestication in native range ca. 5400 BCE; B, ca. 2000 BCE; C, ca. 900 BCE; D, ca. 400 BCE; E, ca. 600 CE onwards; blank, no data. Source: After Perry-Gal et al. 2015; Woldekiros and D'Andrea 2016; Matisoo-Smith 2015). Bottom: earliest zooarchaeological representation and (where available) changing frequencies (percentage number of identified specimens (% NISP) relative to domestic mammals). Straight lines indicate presence from earliest introduction.

culture-contacts that facilitated the chicken's spread across the regions. The data suggest that domestic chickens formed part of a broader group of plant and animal translocations made by the small-scale maritime communities of the Indian Ocean, which established exchange routes between South/Southeast Asia, India, Arabia, Africa, and the Near East during the Bronze and Iron Ages (Fuller et al. 2011). Evidence from the southern Levant suggests that chickens arrived in the Middle Bronze Age (ca. 2000–1500 BCE) and had become well established by the fourth century BCE, when we have the earliest directly dated

chicken remains from the region (Perry-Gal et al. 2015). For Africa, ^{14}C dating of chicken bones from northern Ethiopia has returned dates of ca. 921–801 BCE (Woldekiros and D'Andrea 2016), and it would appear that they were introduced to the continent via the Horn of Africa, most probably from Arabia.

From these regions, chickens spread around the Mediterranean, arriving in small numbers around 800 BCE. Their initial introduction to northeast Europe and Britain occurred a few centuries later, at about 500 BCE, but it took far longer for them to become established in the

colder climates of Scotland, Norway, and Iceland, where chickens are not apparently present before ca. 800 CE (Figure 1). The climatic requirements of chickens—that they are a warm-loving species—highlights that biogeographical spread is not simply about human will: rates of diffusion are, in part, dictated by physiology, as species often need time to adapt to new environments before they can be moved further still from the conditions of their native range.

The significance of environmental conditions for the establishment of species should not be underestimated, and it may be that the dramatic climatic cooling of the mid-sixth century CE caused the declines in chicken populations seen across much of Europe at approximately that time (Figure 1). Certainly, the Roman-introduced populations of fallow deer, another warm-loving species, appear to have become extinct in northern Europe coincident with the sixth-century cold-snap. Modern British fallow deer populations descending from a second introduction appear to have occurred sometime in the eleventh century CE (Sykes 2014, 96). Fallow deer are not the only species that have been introduced to regions on multiple occasions; indeed, repeated introduction events are likely to be the norm rather than the exception. Fascination with identifying the “earliest” examples of non-native species is, therefore, leading researchers to overlook the subsequent biogeographical dynamics that are often more complex and provide equally rich information concerning past environments and societies.

Birds

DALE SERJEANTSON

University of Southampton, UK

Birds have been significant to people throughout human history, as seen from depictions in paintings, carvings, and on pottery. Bird remains are an important source of information about relationships between people and birds. Bones, and sometimes feathers and eggshells, show that birds were hunted and kept for many reasons and not just for food. This entry summarizes techniques of bird bone analysis and describes some of the more striking examples of relationships between people and birds. Where no reference is cited, details can be found in the relevant chapters of *Birds* (Serjeantson 2009).

Analysis of bird bones

Until the 1980s, reports on bird bones discussed the significance of these bones mainly in terms of the environment and past distributions. While these factors continue to be important, archaeologists today are more concerned with interpreting human activities. The zooarchaeological techniques used for bird bone study differ in some details from those used for mammals. Bird bones survive in alkaline soils, but only those of large birds are recovered if screening (sieving) is not practiced. Different meshes are appropriate, depending on the species that are likely to be present (Baker and Worley 2014; see also ENVIRONMENTAL ARCHAEOLOGY).

Many species are skeletally similar so to identify bird bones, the zooarchaeologist needs to have access to a comprehensive reference collection. Even the best identification manuals (e.g., Tomek and Bochenski 2009a, 2009b) can serve only as an introductory guide. Some skeletal elements are unfused at hatching and unite later, but in general bird bones do not have separate epiphyses and age estimation is based on bone length

and on the porous appearance of juvenile bone, as shown for chickens by Thomas, Sadler, and Cooper (2016). A sex ratio is not easy to establish. Some birds are sexually dimorphic—for example the bustards (Otidae), in which the males are much larger than the females, and birds of prey, in which females are larger than males. In chickens and other Galliformes, the males have a spur on the tarsometatarsus. Female birds in lay produce medullary bone in the marrow cavity; this is sometimes seen especially in bones of domestic hens. Cut marks, chop marks, and burning are important guides to human activities. It is crucial to take into account the deposition, context and associated finds to fully understand the significance of birds in ritual. Methods of analysis are set out in detail in *Birds* (Serjeantson 2009, 34–98).

Domestic birds

Domestic birds have contributed much more to human diet than wild birds. At least 27 species of birds have been domesticated at some time in the past, and others have been tamed. Some birds were domesticated for their feathers, others as pets. The main domestic birds kept for food are the domestic chicken, the turkey, two types of geese, and two duck species.

Of these, the chicken is the most widespread—indeed, today it is the most successful domestic animal on earth in terms of absolute numbers. Its prehistory is poorly known. Its ancestor, the wild jungle fowl (*Gallus gallus*), which is now virtually extinct, occupied the foothills of the Himalayas. From there it spread north to China, south to the Polynesian archipelago, and west—through Afghanistan, Iran, and the Middle East—to the Mediterranean and East Africa (see BIOGEOGRAPHY). The first domestic chickens were used in rituals, which included cockfighting. In ancient Greece and Rome chickens were often chosen for sacrifice in temples, cemeteries, and also in domestic contexts. Later they were kept for meat and eggs. Three characteristics of chicken bones are guides as to how

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0064

chickens were being exploited in the past: the sex ratio, the age at death, and the prevalence of medullary bone in laying hens. By the middle of the first millennium BCE chickens were being kept intensively for food (Perry-Gal et al. 2015). In medieval Britain, between the eleventh and the sixteenth centuries, there is a contrast between wealthy households with many immature birds and urban areas where more bones come from adult hens.

The natural range of the domestic turkey (*Meleagris gallopavo*) extended throughout central and northern Mexico and the eastern and southwestern United States. Bones from Preclassic Maya sites show that the turkey had spread beyond its original range by the beginning of the first millennium CE. Its domestic status was confirmed through aDNA and morphological analysis (Thornton et al. 2012). Like the chicken, it was not kept merely for food, but also for its feathers.

Two goose species have been domesticated: the greylag (*Anser anser*) and the swan goose (*A. cygnoides*). The first was domesticated in Eurasia, the latter in East Asia. Greylag geese do not reproduce as prolifically as chickens, but the feathers were highly valued. In medieval Europe quill feathers were used as writing implements and the down is still collected today. When the ulna and carpometacarpus—that is, the wing bones to which the feathers are attached—are found in large numbers, we can infer that they were collected for the quills. Geese naturally moult and grow two sets of feathers each year, so geese were kept for this secondary product.

The two duck species that have been domesticated are the wild mallard or common duck (*Anas platyrhynchos*) and the Muscovy duck (*Cairina moschata*). The initial domestication of the common duck may have taken place in Asia or Europe, as this species coexists commensally with people throughout its range there. It was domesticated from about the first century BCE, or possibly earlier. The Muscovy duck comes from Central America and the northern part of South America and there is dispersed evidence for its domestication from the first millennium CE.

Wild birds

People have been catching wild birds since the Middle Pleistocene, but remains are so scant that birds could never have been a regular source of food. It is only from Upper Palaeolithic times that any systematic exploitation of birds began; in periglacial regions of Europe the ptarmigan was sometimes caught using snares, a method also used for small game.

The only people who have relied on wild birds for food were groups who colonized new environments, especially islands. They encountered breeding birds unaccustomed to predation. Invariably exploitation wiped out the breeding population after a few years, and people changed to catching more sustainable prey. The most dramatic example is New Zealand, where large land birds, the moa, had evolved. After the Polynesians colonized the islands they exploited the moa heavily and the birds were wiped out within 200 years (Worthy and Scofield 2012).

The role played by wild birds in human foodways has been greatest at high latitudes and on islands. This is evident in Patagonia, northern Canada, Greenland, and the North Atlantic islands. The most profitable birds to target were those that bred in large colonies, from which they could be harvested at one season of the year. This mode of exploitation was often sustainable, though it brought about the local extinction of some colonies and the extinction of the flightless great auk (*Pinguinis impennis*). The main species targeted were from the shearwater, cormorant, gannet/booby, and auk families. These birds are nutritionally rich because their bodies have a high percentage of fat.

Communities that lived near wetlands often exploited waterfowl, especially ducks, geese, and coots, although, weight for weight, these birds are less nutritious than seabirds. Geese and ducks were caught when they congregated in flocks at moulting time and their flightlessness prevented them from escaping. Once falconry became popular in medieval Europe (see below), the consumption of wild birds became an emblem of wealth and status rather than a matter of survival.

Feathers

The feathers of wild and of domestic birds have been sought after for their decorative as well as for their useful qualities, especially in the tropics, where many birds have a vivid plumage. Feathers were worn by shamans and other spiritual leaders, to symbolize their ritual authority. Feathers themselves survive only under particular conditions: in anaerobic sediments, in conditions of extreme cold, as in northern Canada, or in arid environments. The identification of feathers from their morphology is a specialized skill that will be facilitated by the development of aDNA and ZooMS (Stewart et al. 2013).

From the modified wing bones of crane (*Grus grus*) at Catal Huyuk it was deduced that the feathers had been worn, probably for dances that imitated the crane's nuptial dance. Some birds were domesticated for their feathers alone. The scarlet macaw (*Ara macao*) was domesticated in Mexico and the southern part of the United States: breeding in captivity was confirmed at Paquimé, in Mexico, where isotopic analysis of the bones showed that the macaws had been bred locally rather than procured from their natural range further south (Somerville, Nelson, and Knudson 2010).

Cockfighting and falconry

Some pastimes involve birds: historically, the most significant were cockfighting and falconry (hawking). Cockfighting has a long history in Asia, Europe, and the Americas. In the wild, roosters fight to breed with hens, and this natural behaviour was encouraged. Fights were staged to foretell the outcome of battles and other events and to teach the virtues of aggression in battle. Where greater numbers of male birds than would be expected are present in a domestic flock, this can suggest that cockfighting was the main reason for keeping the birds (Sykes 2012).

For centuries, falconry was an important means of displaying status, both in the Middle East and in Europe. It began in the first millennium BCE in Asia and spread to Europe and the Middle East in the first millennium CE. Falcons are not usually bred in captivity but

are captured in the wild, and their training is a highly specialized skill. Evidence for falconry comes from remains of the raptors themselves, and also from their typical prey species: each raptor was set to fly at prey of a certain size. As it is possible to identify the sex as well as the species of raptors, it is also possible to identify the social rank of the individual who owned the bird.

Symbolic significance of birds

Zooarchaeological evidence that birds had symbolic value for people is elusive, but occasionally it can be found. A bird regarded as a totem animal might be depicted but would not be killed. In many societies, birds were associated with the gods. In Egypt some were tamed and mummified. Birds in flight were regarded as messengers between the gods and humans; for the Romans, the flight of birds foretold the future. All over the northern hemisphere the raven and the crow were seen as birds that communicated with the gods through their power of imitating human speech, and for this reason were taboo as food. They could be tamed and were the ritual companions of shamans or powerful men in northern Europe in the first and early second millennium BCE.

Future

The ability to identify bird bones and feathers from their chemical signature (ZooMS) is going to transform our understanding of birds in the past. This technique also assists the identification of eggshell (Stewart et al. 2013), something that has been difficult until now. The analysis of aDNA will continue to contribute to separating species and was successful with the New Zealand moa. Stable isotope studies reveal ancient as well as modern migration and movements. So long as the study is approached with archaeological and anthropological goals, the range of insights that can come from bird bones is surprisingly wide, especially in view of the relatively small number of bird bones found on most sites.

Cattle

ELIZABETH WRIGHT

University of Sheffield, UK; Northern Archaeological Associates Ltd, UK

Cattle have been among the most important animals for humans for hundreds of thousands of years. Alongside the domestication of the pig (*Sus domesticus*), sheep (*Ovis aries*) and goat (*Capra hircus*), that of cattle was a vital part of what is known as the Neolithic revolution, which saw a shift from hunting and foraging to agriculture. This transition has enabled humans to selectively breed cattle populations for different products such as meat, milk, and labor and to genetically “improve” their stock in order to increase and specialize production and sustain herds.

The aurochs (pl. aurochs, or more rarely aurochsen; *Bos primigenius*) is generally considered to be the extinct wild ancestor of domesticated cattle. This wild species first appeared during the Pleistocene and finally became extinct in 1627, when the last animal died in Poland. The exact origins of the aurochs are not clear; it is thought to have Indian ancestry, being possibly related to *Bos acutifrons*, which dates back to 2 million years ago and lived in the Siwalik Hills of northern India, and also to two other Asiatic species, *Bos planifrons* and *Bos namadicus*. Aurochs remains in Europe have been studied more intensively than remains in other areas, owing to their frequency across the continent and to a tradition of research there. Owing to the long history of the aurochs, their remains have been of interest to paleontologists as well as to zooarchaeologists and biomolecular archaeologists.

Paleolithic and Mesolithic humans regularly hunted aurochs alongside red deer (*Cervus elaphus*) and wild boar (*Sus scrofa*). The geographical distribution of the aurochs fluctuated with the changing climate, as populations retreated to southern areas during cold periods, but at its peak aurochs could be found anywhere from the Atlantic coasts of Europe to the Pacific coasts of

China, as well as in North Africa. No remains have been found in Ireland, which makes the west coast of Iberia the westernmost extent of the range. There is no evidence of the species having crossed the Bering Strait into America. Morphometric study has revealed that the body size of the aurochs varied geographically within Europe, aurochs in northern areas having on average a larger body size than in southern areas during both the Paleolithic and the Mesolithic, in line with thermoregulation (Wright and Viner-Daniels 2015).

The aurochs is thought to have lived in predominantly forested areas. Pollen analysis has shown that most of its distribution area was forested and that it survived longest in the forest landscape of Bialowieza, in east Poland. Additionally, studies of nitrogen and carbon isotopes (see ZOOARCHAEOLOGY AND STABLE ISOTOPES) from Danish aurochs remains have indicated that this animal had a diet with high ¹⁵N values and low ¹³C values—a pattern in line with feeding on litter from the forest floor (Noe-Nygaard, Price, and Hede 2005).

Almost all modern domesticated cattle (see DOMESTICATION) can be attributed to two recognized forms—the humpless taurine cattle of Europe, west Africa, and northern Asia (*Bos taurus*), and the humped zebu cattle of southern Asia and Africa (*Bos indicus*)—and the aurochs is thought to be the wild ancestor for both. A combination of zooarchaeological, genetic and isotopic studies has contributed to the discussion surrounding where and how cattle were domesticated and how the domestic form spread across the world.

It is now generally agreed that there were two independent domestications of cattle worldwide; one resulted in a lineage that included *Bos taurus*, which most likely appeared in the Near East more than 10,000 years ago, and the other contained *Bos indicus*, which appeared on the Indian subcontinent a little later (e.g., Loftus et al. 1994; Troy et al. 2001; Chen et al. 2010). These two species are thought to have been moved by humans respectively across Europe and across

Asia and Africa, with limited interbreeding with local wild aurochs along the way.

The identification of wild and domestic cattle bones has been integral to the debate around cattle domestication, as correct identification can indicate the presence of the wild form, the dispersal of domesticates, and, through this, the pattern and chronology of domestication events. There are very few morphological differences between the two species, but the process of domestication led to a reduction in body size; as a result, morphometric methodologies have long been employed in order to distinguish the species from each other. There is, however, a size overlap between wild and domestic forms that is related to sexual dimorphism: in other words, small female aurochs may overlap with the larger domestic males. Additionally, geographic variation in body size, particularly in wild cattle, has also complicated the distinction between wild and domestic forms. Nevertheless, our understanding of these issues is improving, and biometrical data combined with other zooarchaeological information on age profiles and sex ratios have enabled archaeologists to identify the earliest evidence for cattle domestication in the Near East and to track the movement of domestic cattle across Europe.

A growing body of genetic work (see ZOOARCHAEOLOGY AND ANCIENT DNA) has also been employed to investigate cattle domestication. Most of this work has dealt with mitochondrial DNA (mtDNA). The basis for this work has been the identification of a domestic *Bos taurus* haplogroup “T,” which can be further divided into subgroups T, T1, T2, T3 and T4, and a wild *Bos primigenius* haplogroup “P.” A different haplogroup, named “I,” has been found in *Bos indicus*, which has two sub groups, I1 and I2. Extensive work on the domestication of European cattle, however, has identified a number of other potential *Bos primigenius* haplogroups (e.g., Q and E), indicating that the situation is more complex than originally thought. Further work on mtDNA alongside an increasing number of studies that look at nuclear DNA is likely to further our knowledge in this area in the future.

The domestication of cattle, as that of other farm animals such as caprines (see SHEEP AND GOATS) and pigs (see PIGS), allowed humans a degree of control over a population that could

then be bred to achieve particular selected traits. Both wild and domestic cattle have been exploited by humans for their meat, but domestic populations were also bred for “secondary products,” which can be procured from an animal while it is still alive. It is now clear that domestic cattle were being exploited for both milk and labor from an early date after domestication, and that these are therefore not recent innovations.

Numerous scientific techniques have been used to investigate what products domestic cattle populations were exploited for. Zooarchaeologists use mortality profiles, where models representing typical meat, milk, and traction economies (Legge 1981) are used to aid interpretation. This information should be combined with other zooarchaeological data in order to provide a more reliable interpretation. A typical dairying population (see DAIRYING), for example, is thought to have a high peak of young (predominantly male) calf deaths along with an aging population of predominantly female animals. A population of cattle killed mostly at an older age may indicate that this is a population used primarily for its labor, but this interpretation is much stronger when combined with pathological evidence linked with the impacts of mechanical stress.

Cattle populations have also been “improved” at various points during history, through the inbreeding of newly imported and larger cattle types. A typical example can be seen during the expansion of the Roman Empire across Europe (from the first century BCE onwards), when new, larger Roman cattle were transported to new areas, where smaller Iron Age cattle had previously been dominant. The presence of these large cattle is detectable through analysis of measurements taken on both bones and teeth, as part of zooarchaeological study. This presence has been used as evidence for the process of Romanization, and therefore has wider implications for studies of the spread and extent of Roman influence. The introduction of so-called improved breeds has been detected, with the help of these techniques, in a wide variety of individual contexts and also across broader timescales, which can be linked with agricultural innovations. A notable example is a size increase in cattle, and indeed in other livestock, in Britain, from the sixteenth century onwards, a phenomenon attributed to a shift in

agricultural practices that led to the agricultural revolution (Davis 1997).

Zooarchaeological study can be supplemented by targeted biomolecular work in order to give us a clearer picture of the mechanisms of cattle improvement and their links to cultural change. In the case of Roman Britain, for example, evidence from strontium isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) in cattle tooth enamel from the site of Owlesbury indicated growing diversity in the geographical origin of cattle during the Roman era by comparison to the preceding Iron Age, which correlated with an increase in body size seen through the biometrical approach and with other evidence for the opening up of the trade network (Minniti et al. 2014).

Cattle have continued to be exploited for a variety of different products down to the present day; such products include beef, veal, dairy and leather and they have great economic and social importance across the world. The domestication of cattle was one of the most significant agricultural innovations ever achieved by humans, but it is sometimes easy to forget that our relationship with this animal goes back much further in time and that cattle are in fact more ancient than our own species. We would do well to remember not to take these animals for granted and to view their modern exploitation critically.

Caves and Fissures

SUSAN M. MENTZER

University of Tübingen, Germany; Senckenberg
Centre for Human Evolution and Palaeoenvironment,
Germany

Caves, rockshelters, and fissures are a unique group of geomorphic features in that they are, in part, defined by their accessibility or functional role with respect to humans. Gunn (2004, Editor's Introduction) defines caves as "natural openings, usually in rocks, that are *large enough to permit entry by humans*" (emphasis added). Likewise, rockshelters can have many morphologies, but must always afford their occupants some degree of protection from the elements. Caves and rockshelters are also sometimes distinguished by dimensions and lighting: Caves are deeper than they are wide and have unlit zones, while rockshelters are wider than they are deep. Fissures lack roofs, and are predominantly vertical in orientation, but are still of significant size that humans or their livestock might fall inside. The term "cavity" can be used to describe any type of cave, shelter, or fissure.

Several classification systems exist for both caves (White and Culver 2012) and rockshelters (Mentzer 2016). Typical approaches include grouping by formation process, bedrock, and morphology. For archaeologists, knowledge of classification systems is useful for understanding how people might have used cavities, and how the morphology, bedrock composition, microenvironment, and other occupants may have contributed to deposition, erosion, and preservation of archaeological materials. For example, deep cave systems formed in limestone can contain multiple types of archaeological sites ranging from deeply buried occupation debris in moderately lit entrances, to surface finds of ritual deposits in the dark recesses. Alkaline dripwater and calcareous speleothems—which contribute to preservation of archaeological materials such as wood, ashes, and bone—are

most common in karstic systems, but have also been documented in sandstone sea caves and basaltic lava tubes. Vertical shafts, such as those found in fissure caves, pit caves, and dolines accumulate archaeological materials and human remains as a result of passive movements (e.g., erosion, accidental falls) or active discard (e.g., waste dumping, murder).

As features that are by definition accessible to humans, it is not surprising that our species and its ancestors have utilized caves, rockshelters, and fissures in many ways. These features have particular significance in paleoanthropology, because cavities have geologic longevity and functioned as natural sources of shelter and also traps where skeletal remains could accumulate (Dirks and Berger 2013). During the Early and Middle Pleistocene, cavities became repositories for a significant number of skeletal remains due to accidental falls, suffocation, or hunting and scavenging by carnivores. Even in the Late Pleistocene and Holocene, cavities remain valuable find localities. A majority of Neanderthal remains and the earliest anatomically modern humans recovered outside of Africa were discovered in caves. *Australopithecus sediba*, *Homo floresiensis*, *H. naledi* and the Denisovan subspecies are known only from remains found in caves.

Beginning in the Lower Paleolithic, hominins also utilized cavities as sources of shelter, water, and raw materials. Middle and Upper Paleolithic people diversified their uses of caves to include localities for burial, ritual behaviors, and parietal art. In the Neolithic, humans began using cavities as stables for livestock, developing maintenance behaviors such as seasonal clearing, foddering, and finally burning of accumulated dung which produces a deposit known as *fumier*. Cavities have also been used as crypts, storage areas, waste repositories, mines for mineral resources and guano, quarries, and recreational exploration. Unique microenvironments make some cave systems well suited for the storage of perishable materials, with some functioning as natural refrigerators or desiccators. For example, the dry caves of North America have yielded a rich record

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0074

of perishable organic artifacts, including shoes, baskets, and clothing. Humans also construct architectural features in cavities, ranging from windbreaks and gateways to entire structures or villages (e.g., cliff dwellings of the American Southwest). Humans continue to use caves for habitation today, and ethnographic observations of use of space and material discard patterns have helped inform our interpretation of the archaeological record.

Scientific analyses can be applied to any archaeological materials recovered from cavities; however, there are some approaches that require specific consideration of the cave environment. These include the study of site formation processes, geochronology, remote sensing, and paleoenvironmental reconstruction. Several archaeological science techniques described below were either first applied in cave and rockshelter settings, or were specifically developed in order to address research questions that are unique to these types of sites.

Site formation processes

The most common application of archaeological science to cave and rockshelter sites is the study of formation processes of the features themselves coupled with a reconstruction of infilling, and sometimes erosion (see GEOARCHAEOLOGY and FORMATION PROCESSES). Comprehensive summaries of cave and rockshelter geoarchaeology are provided by Farrand (2001) and Goldberg and Sherwood (2006). Geoarchaeological approaches include both field and laboratory analyses. Documentation of the stratigraphy, expedient estimation of sediment texture, description of color and visible inclusions, and acid tests are carried out during, or immediately following excavation, and can aid in grouping archaeological materials by sedimentary unit. Laboratory analyses are conducted with the aim of further describing sedimentary units, correlating units across the site, and identifying sediment sources and postdepositional processes and include particle size analysis, calculation of calcium carbonate abundance, and micromorphology (see MICROMORPHOLOGY). Some analyses, such as measurements of elemental abundance using

X-ray fluorescence, and identification of primary and secondary minerals using Fourier transform infrared spectroscopy (FTIR; see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) can be conducted in both the field and laboratory. The latter technique was specifically developed for the study of diagenesis (see DIAGENESIS OF BONE) in caves (Karkanas et al. 2000).

The main sources of sediment in caves and rockshelters can be classified into autochthonous and allochthonous, while modes of sedimentation can be geogenic, biogenic, and anthropogenic (Farrand 2001; Goldberg and Sherwood 2006). Autochthonous sediments derive from within the cave system. An example of a geogenic autochthonous sediment is a layer of bedrock fragments derived from roof collapse (*éboulis*), while an example of a biogenic autochthonous sediment is bat guano. Both of these sedimentary facies are unique to cave, rockshelter, and fissure settings. Allochthonous sediments derive from outside the cave system, and can range from silts with an aeolian (geogenic) mode of deposition to clay floors of anthropogenic origin. Reconstructing the source and mode of deposition is one of the first steps in understanding the formation history of an archaeological site, and can lead to further avenues of investigation. For example, *éboulis* layers can mark the location of former overhang positions, which aids in modeling the morphology of the cave or shelter over time. The identification of guano in a site has implications for the timing of human occupation relative to other animals, the preservation of archaeological materials, and even the possibility of recovering paleoenvironmental indicators.

Although soil-forming processes can and do impact sediments within caves and rockshelters, the expression and intensity of postdepositional weathering can be very different compared to open air sites. For example, clay translocation can be spatially constrained due to the presence of dripping water along the brow (the so-called dripline) and bedrock joints. Dripwater and pore water have more variable composition within cave environments, ranging from strongly acidic to strongly alkaline depending on bedrock composition and the presence of sedimentary components such as guano or wood ash.

In cave environments, secondary cementation of sediment can yield a cave breccia that on one

hand aids in the preservation, but on the other hand can make excavation exceptionally difficult. Some strategies for dealing with these types of deposits include drilling, jackhammering or controlled explosions which allow archaeologists to remove large blocks for more careful excavation in a laboratory setting. This approach has been utilized for a number of sensitive skeletal remains, including Australopithecines from the Sterkfontein caves of South Africa.

There is much focus in the archaeology of caves and rockshelters on sedimentation and postdepositional alteration, which leads to the generalization that caves and rockshelters are sediment traps. The mode and intensity of erosion (see *EROSION*) from these types of sites is dependent on the geomorphic setting. Cavities located in coastal and fluvial regimes can be inundated and eroded by water; changes in base level in the same settings can also initiate slope instabilities outside of the cavities, resulting in colluvial movement. Erosion of deposits can also occur within cave systems as a result of sinkhole formation and slumping, or internal and external breaching of bedrock. Even cemented sediment can be impacted. Weathering of breccia and formation of new cavities within is a process that characterizes many of the sites in the Cradle of Humankind (see Dirks and Berger 2013).

Imaging techniques

As described above, archaeological excavations in caves are made difficult by some components of cave sediments, such as large blocks of bedrock and cave breccia. In some cases it is useful to have prior knowledge of the sediment depth and composition prior to testing. Penetrometers have been employed in order to obtain rough estimates of sediment depth (see *SOIL PENETROMETRY*). Ground-penetrating radar (see *GROUND-PENETRATING RADAR*) has the additional advantage of being able to image subsurface sedimentary layer boundaries in addition to bedrock topography. The complex morphology of some cavities can also prevent more typical approaches to mapping sites. In these cases, modeling of caves, rockshelters, and fissures can be achieved using laser scanning (see

LASER SCANNING), LiDAR, and photogrammetry (see *IMAGE-BASED 3D MODELING* and *LIDAR DATA VISUALIZATION AND PROCESSING*). These approaches have the advantage of generating three-dimensional models that can then be used to produce views of the entire cave system or specific areas of archaeological significance.

Dating techniques

Nearly any dating technique can be employed in cave and rockshelter settings, although some caveats may apply. For example, in cave sites, uncertainties in modeling changes in environmental radiation can negatively impact the precision of ages produced by optically stimulated luminescence (see *OPTICALLY STIMULATED LUMINESCENCE*) and electron spin resonance (see *DATING AND ELECTRON SPIN RESONANCE (ESR)*). Likewise, ongoing weathering of bedrock and complicated infilling and erosion histories can make cosmogenic dating (see *COSMOGENIC DATING*) more difficult compared to open-air settings. Conversely, cave systems can be ideal locations for the application of uranium-series dating (see *URANIUM-SERIES*), as speleothems may form within or on top of archaeological deposits.

Paleoenvironmental reconstruction

In the 1960s–80s archaeological research on caves and rockshelters was dominated by regional studies that attempted to correlate deposit types with broad paleoclimatic conditions. In French Paleolithic sites, *éboulis* layers were attributed to cryoclastic processes during glacial periods (see Laville, Rigaud, and Sackett 1980). More recent work on this topic, summarized by Woodward and Goldberg (2001), emphasizes that while individual cavities may preserve deposits indicative of local environmental conditions, regional correlations are problematic and best avoided. Nevertheless, some paleoclimatic studies can provide information about the immediate local environment with a high degree of chronological control. Measurements of stable isotopes of oxygen, carbon and hydrogen; major and trace elements; and even sediment inclusions can be conducted on laminated speleothems, such as stalagmites, with chronology provided by uranium-series or

radiocarbon dating. The Pinnacle Point complex of South Africa is one example of a cave and rockshelter cluster that contains a speleothem record in addition to several contemporary archaeological sequences. Other types of local archives in cave sites include sediment containing magnetic particles, diatoms, pollen, microcharcoal, and other environmental proxies. Some deposits, such as lacustrine sediments and guano have the potential to yield records with an annual scale of resolution. Finally, geoarchaeological analyses of sediment can reveal fabrics, structures, and microstructures, such as ice lenses, that have significance for local climatic conditions at the time of formation.

Charcoal and Wood Analysis

ROBYN J. VEAL

University of Cambridge, UK; University of Sydney, Australia

Wood and charcoal analysis provides us with the tools to examine ancient wood cultivation and consumption habits, and contribute to understanding ancient economies. Almost any type of wood was used as fuel and virtually all types are found in the archaeological record. “Preferred” woods in Europe were (dried) hardwoods, such as oak, beech, maple, and hornbeam. In the tropics, a range of woods were available from coastal mangroves to forest hardwoods, many from the Dipterocarpaceae family. European hardwoods provide a fairly similar average calorific (heat) potential, while tropical hardwoods are, on average, denser and can potentially supply more calories for the same weight.

European hygrophilous woods (those living close to water such as alder), have a lower average calorific potential because of their higher water content. Water needs to be driven off before the calorific value of such woods can be realized. This is true also of tropical wood types. If woods with an inferior lower calorific potential are employed, then a greater quantity of the wood will be required to achieve the same temperature, all other factors being equal. Drier climate woods often found in Mediterranean climes, called “macchia” or “macquis,” make good fuel although they often consist of small and prickly branches that are difficult to collect, and often produce unpleasant smoke.

Preferred timber woods were usually those deciduous and evergreen hardwoods that produce long and strong planks, especially oak in Europe and teak or ebony in the tropics. However, in shipbuilding, conifers such as silver fir, high altitude mountain pines, and cypress occur in the archaeological record. Cedar, while recorded in the ancient literature, especially in Egypt, and

the Eastern Mediterranean, is yet to be found archaeologically in any quantity other than for sarcophagi, and funeral furniture. This is most probably due to limited work on shipwrecks from these areas.

Collection of fuel woods by ancient peoples has often been interpreted as being governed by the “Principle of Least Effort” (Shackleton and Prins 1992). However, recent research shows that even in early prehistory, woods may have been collected according to their calorific value, or perhaps for other social reasons. From broadly 3300–1200 BC, selectivity increases, along with the use of charcoal as a fuel.

Wood in the archaeological record

Wood may be preserved in the archaeological record in several forms: petrified (usually pre-Paleolithic), mineral-replaced (where salts replace the wood structures), mineral preserved (where preservation occurs due to the effect of metal corrosion products (see FORMATION PROCESSES), desiccated (especially in parts of Asia, Africa, and the Aegean), wet (in anaerobic conditions, for example in Northern Europe), and charred. The latter two forms of preservation are the most common and require slightly different approaches to analysis.

Wet woods are analysed while still wet, that is, before conservation. Whole timbers are collected, or samples are taken, usually by a specialist. Identification proceeds after the sectioning using a microtome or hand blade, followed by mounting on slides. A cryotome (which freezes the sample) may be used for sectioning fragile material. Three sections in different planes are required for identification: transverse (“across” the grain); longitudinal (“down or with the grain”); and radial (longitudinal, following the round of the wood).

Collection of charred wood (charcoal) takes place during excavations, as for other material culture. Collection using dry sieving is preferable. Flotation, undertaken for the collection of seeds, microfauna, and other small items, is less

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0081

helpful for archaeological charcoal as it leads to fragmentation. Experiments have established that the fraction >4 mm provides the best results in terms of representation. Collection strategies up to now have focused on primary deposits such as hearths, ovens and so on, but these provide only a limited view of the last, or last few burn events. Randomized, but systematic spatial and temporal sampling (see SAMPLING IN ENVIRONMENTAL STUDIES and SAMPLING THEORY) is preferable to obtain an overall view of the woods consumed for a particular time period and location. After consulting the stratigraphic record, auditing of charcoal preservation levels, and gaining an understanding of the reporting goals for the site, the wood and charcoal analyst is able to make decisions about the quantity of identification work required. Frequency curves are used to determine sampling adequacy. These plot the number of fragments (x axis), against the unique number of taxa identified (y axis). As identification proceeds, fewer unique taxa will be discovered. A “saturation point” is often reached at about 20 percent of the fragment count (where about 80 percent or more of the unique taxa will have been discovered). The curve observed is usually a steep “S.” After this point, the majority of the taxa will have been found, and so identification can conclude and the optimal fragment count for the assemblage gauged. For areas of low floral diversity (for example, Roman Britain), examining around 50–100 charcoal fragments per context can prove sufficient, while for the Mediterranean, where diversity is often higher, 250–350 fragments are more commonly examined per time period or context. Specialists review the optimal fragment count required during analysis, especially if changes occur in wood type or size as new contexts are examined.

Charcoal may be fractured by hand, or using a scalpel, to produce sections in three planes as for wet wood. Both wet and charred woods retain most of their cellular structures even after long-term deposition, and so identification under a compound microscope (x10–x400), can often be made to species level, although resolution to genus or only family level are common. Modern reference collections, as well as atlases, assist identification (Wheeler and Brown 2004; Schweingruber 1990). In addition to species identification, analysts also make observations about

presence of mineral and other inclusions which can relate to preservation conditions, cultural use, or both (see TAPHONOMY). For example charred *hyphae* can indicate the use of dead or cropped wood, while uncharred *hyphae* demonstrate postdepositional fungal damage.

Estimation of wood diameter and curvature are employed to analyze cropping and management strategies. Wood remains must be around 4–5 mm in cross-section for measurement to be possible. Curvature is usually classified according to a scale from straight—no or low curve—indicating the use of “large” wood, perhaps over 50 cm in diameter, to highly curved, indicating the use of twigs and small branches (Marguerie and Hunot 2007). Diameters may be estimated if a specimen retains both the pith and bark, although allowance for shrinkage from the charring and burning process must be made. Charred woods shrink from 10–25 percent depending on size of the original branch and type of wood. Diameters can be estimated using a traditional ceramic template or using the mathematics of isosceles triangles (Dufraisse 2006). The former is faster, but potentially more error prone; the latter is generally more accurate but takes longer. Both are subject to the vagaries of variability in wood growth. Results are usually grouped by diameter classes and used to show the use of “small,” “medium,” or “large” woods, with the goal of relating any changes to selection or cultural behaviors, environmental factors, or both.

Ancient charcoal production

The production of charcoal was, and is, a rural activity. Charcoal fuel will provide about 1.8 times the calorific potential of fresh wood and was the preferred fuel in cases where consistent temperature was required. Charcoal also burns with little or no smoke, and provides an even and “spit-free” heat. It is about one-third the weight of wood (by volume).

Wood charcoal fuel is made from a quantity of raw wood arranged in a stack (or pit). “Charcoalification” (as opposed to combustion) occurs in an oxygen-depleted atmosphere. Quantities of wood were usually cut to measure (about 1 m long), and the stack ignited (Veal 2012). Oxygen depletion

was achieved by covering the stack with soil or leaves and charcoal dust. Access to water was essential (to prevent full ignition of the stack). Charcoal making has been presumed to be an easy and almost spontaneous task, but the opposite is true. Care to cut wood (in fall or winter), then sort, stack, and dry it is required. Charring (usually in summer), requires a high level of technical skill, and this precludes economic quantities of charcoal being made without considerable planning, although charcoal can be made relatively easily in small quantities. It is probable that early humans discovered the utility of charcoal well before its use escalated in historical periods, although the matter has not been explored.

Observation of archaeological charcoals, together with ethnographic evidence, suggest that ancient charcoal fuel was made using different “recipes” depending on its intended use. Charcoal for domestic use can be made at the rate of 4–5 volumes of wood to produce 1 volume of charcoal (to produce a product that is about 65 percent carbon). This process retains some of the organic volatiles so that later combustion is facilitated. For industrial uses such as iron smelting a higher quality product (perhaps 80–85 percent carbon content) is required (Schenkel et al. 1998, 515), taking a minimum of 10–12 volumes of wood to make 1 volume of charcoal. This raises the question of how much charcoal as opposed to raw wood was consumed. Reflectance, a technique used in coal provenancing, relies on the observed “shininess” of a fractured charcoal being linearly related to its absolute burn temperature. It is currently being employed to try to resolve this question (Veal, O'Donnell, and McParland 2016).

In a big city, charcoal fuel may have been the preferred domestic fuel partly as it would have been cheaper to transport. The size of portable cooking hearths and the closed nature of heating braziers from Roman Pompeii suggest the use of charcoal as fuel rather than wood. Latin sources explicitly state that *carbone* was the fuel of choice in braziers.

Most processes requiring temperatures below about 800–900 °C (ceramic production) do not require the use of charcoal, whereas high temperature processes requiring a reducing atmosphere (above 1100–1200 °C), that is, iron smelting, do (Sim 2003). We cannot presume charcoal was not

used in lower temperature industrial processes, but common sense suggests it is less probable. A further consideration is the type of fire required. Slow, steady fires are best served by charcoal fuel. Technologies that required sudden temperature rises and falls are often best served by raw wood.

Economic modeling

Modeling may be carried out to assess the area of forest required to support the wood fuel supply for a city or settlement. The fuel supply to Pompeii over c. 400 years has been considered in detail (Veal 2012). The model addresses quantitatively a limited range of probable population sizes and possible fuel consumption levels in the city, taking into account relative consumption of charcoal and raw wood fuels, and forest productivity. Results are interpreted in light of the ecology of ancient southern Campania. This model could be applied more widely, providing population estimates may be gleaned, and climate and fuel used estimated.

Companion Animals

JEAN-DENIS VIGNE

CNRS–Muséum national d'Histoire
naturelle–Sorbonne Universités, France

From the beginning of their existence, domestic animals of all kinds played major roles as food, in health, in techno-economic progress, beliefs and religion, social relationships and landscape shaping or management (see DOMESTICATION). Most of them, especially mammals, have woven ever closer relationships with humans. Some even became companion animals, because they lived at least part of their time inside dwellings as intimates of the household. Dogs and cats are the most common type of companion animal. There are roughly equal numbers of dogs and cats in the world today, numbering over a billion individuals, and as such they have major social and economic impacts. Therefore, deciphering the origins and long history of these animal's relationship with humans is almost as important as understanding the origins and history of our own species.

Where and when were dogs and cats first domesticated? How and why did they become companion animals? Have they always been pets? During the last 15 years, these important issues have stimulated intensive archaeological and zooarchaeological research (see ZOOARCHAEOLOGY), including the use of morphometrics and aDNA (see ZOOARCHAEOLOGY AND ANCIENT DNA), resulting in a wealth of new knowledge.

Dog, the domestic animal of hunters

It is clear from zooarchaeological investigations that the wolf (*Canis lupus*) is the unique ancestor of all dogs (*Canis familiaris*; Clutton-Brock 1999). This has been confirmed by the genetic analyses of modern wolves and dogs in conjunction with paleogenetic investigations (Larson et al. 2012).

The earliest evidence for dogs is mostly based on the discovery of *Canis* archaeological skeletal elements of much smaller size than those of smaller modern or ancient wolves. Such skeletal remains appear suddenly at numerous sites between 13,000 and 10,500 cal BC, in France, Switzerland and Germany, and in Spain, maybe as early as 15,000 cal BC. These western Europe Upper Paleolithic small dogs (WEUPSD) are associated with the Late Magdalenian, Azilian, or Laborian cultures (Pionnier et al. 2011). Two other areas in the Old World, north China and the Levant, have provided more or less contemporaneous evidence (ca. 10,500 cal BC) of the presence of small canids that are interpreted as domesticates. The discoveries are still rare in the former area, but in the latter, dog remains have been described from Late Natufian archaeological contexts from southwest Anatolia and the north Zagros to the south Levant, some of them in association with inhumations (Larson et al. 2012). At the Palestine site of Ain Mallaha, a young dog skeleton was found in one of the deceased's hands. In Germany and Russia, large Magdalenian canids, the same size as wolves but with a short snout and a broad palate, are also considered to be early domestic dogs.

For most zooarchaeologists, the occurrence of more or less contemporaneous early dogs in such distant areas pleads for several independent domestication events in Eurasia, anywhere within the wolf's very large distribution range. Contra to this, the first genetic investigation seemed to support an alternative hypothesis, a unique origin in China, followed by diffusion of domestic dogs across the rest of the world, including America and Australia. However parallel analyses of genetic diversity in African village dogs supports the multiple origin hypothesis. More recently, geneticists have established that genetic diversity in modern dogs mostly results from selective breeding from the nineteenth and twentieth centuries and that little or no information concerning the early history of dogs can be inferred from the genetic diversity of the modern populations, meaning that paleogenetic data are

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0102

required to explore the origin and history of this species (Larson et al. 2012). There is clear evidence from the latest ancient DNA investigations that dogs were not domesticated in America, Africa, or Australia, but introduced to these continents as domesticates during the Upper Paleolithic. Recent investigations based on a large aDNA dataset has identified at least two domestication areas, in Europe and Asia respectively (Frantz et al. 2016). Further investigations may increase this number and reconcile molecular and morphological approaches. DNA next generation sequencing (see DNA: NEXT GENERATION SEQUENCING) has already provided information about the apparition of new coat colors and the evolution of the ability to digest starch in the domestic lineages (Ollivier et al. 2016).

It is not impossible that dogs were domesticated earlier in the Paleolithic and even possibly by Neanderthals. In Belgium, the Czech Republic, and Siberia, the discovery of large canids showing broad palates, tooth crowding, and skull proportions different from both modern wolves and dogs suggests that wolves could have been domesticated without any reduction in body size earlier than 30,000 BP. However, subsequent analyses have shown that all the particularities of these so-called early dogs can be accounted for in the much larger domain of variability of ancient and modern wolves (Boudadi-Maligne and Escarguel 2014).

Like Paleolithic human hunter-gatherers, wolves formed complex social groups and developed collective hunting strategies directed at the same middle or large sized prey. The two species fed on the same carcass or even preyed on one another. They used the same caves, with archaeologists finding the coprolites and gnawed bones resulting from wolves' meals, and the chipped stones and fire places left by humans in the same layer. In addition, wolves could have scavenged garbage from human occupation sites or people could have kept and bred cubs as pets. As competitors, collaborators or commensals, wolves weaved multiple ecological and symbolic relationships with humans over millennia across the whole of Eurasia. Ecological, ethological, and ethnological information suggests that domestication appeared as the consequence of one or several of these relationships, when humans began to deliberately accept and even favored the

presence of wolves within their groups. However, archaeology cannot yet tell us how and why this happened.

Neither do we know the role that dogs played in Paleolithic hunter-gatherer societies. Did they help with hunting and driving game, as suggested by some Mesolithic wall paintings in the Sahara or in Spain? Did they tow sleighs? Were they also used to alert people to the presence of other predators or people outside of the group? Did humans already appreciate them as "settlement cleaners?" Were they used for keeping people warm as recently in some Aboriginal societies, in Australia? Were they also pets? Butchery and cooking marks on bones indicate that wolves and dogs were consumed everywhere in the world throughout the Upper Paleolithic, and that their pelts were valued.

With the beginning of the Neolithic, diversity in the shape and size of dogs increased. In some regions at least, their status seems to have shifted from one of hunter to garbage scavenger and guard dog. As close companions of shepherds, they would have played a role in the protection of flocks against predators. However, their bones still appear in small quantities in human food refuse.

With the emergence of empires, in Africa (Egypt), Asia (Persian or Chinese early dynasties), Europe (Greek than Roman) and even America (Clutton-Brock 1999), both iconographic representations and skeletal remains indicate people selectively bred lineages of dogs, namely hounds, huge dogs and small "lap" dogs. However, these early selected lineages played only a minor role in the emergence of modern pedigree breeds which were developed starting afresh from mongrels. Parallel to this recent morphological and behavioral diversification, dogs were used for a wider variety of purposes, e.g., for herding flocks, for sport, and as guide dogs for the blind.

Cat, the domestic animal of cultivators

Zooarchaeological and genetics shows that the ancestor of all modern domestic cats (*Felis catus*) is a subspecies of the wild cat *Felis silvestris* ssp. *lybica*, that presently lives in North Africa and

Southwest Asia (Driscoll et al. 2009). Domestic cats have long been considered to have arisen in Egypt, where paintings indicate that they existed at least as early as twentieth–nineteenth centuries BC (Clutton-Brock 1999). However, skeletal evidence was lacking, because there is very little morphological difference between the bones of wild and domestic cats. Only in some special archaeological contexts can the presence of cat remains be used to suggest domestication, such as the hundreds of mummies deposited in sanctuaries devoted to the goddess Bastet. The recent discovery of such a special context in the Predynastic elite cemetery of Hierakonpolis (a grave containing one male and one female cat skeleton along with four kittens from two different litters) pushes the earliest evidence of cat domestication in ancient Egypt back to 3,800–3,600 cal BC (Naqada IC–IIB period, Van Neer et al. 2014).

Surprisingly, similar evidence has been uncovered in the late deposits of the Cyprus Pre-Pottery Neolithic (PPN) B site of Shillourokambos, dating to 7,500–7,000 cal BC. This revealed that the common history of cats and humans began much earlier in the Levant than in Egypt. A complete skeleton of a large young male cat was found in an inhumation carefully deposited facing the deceased (Driscoll et al. 2009). The association of these two individuals in the grave and consequently in the hereafter suggests strong spiritual links between at least some cats and humans by this early date. In addition, large-sized cat remains have been discovered in numerous early Neolithic archaeological sites in Cyprus contemporary with the first introduction of agriculture to this large Mediterranean island located 70 km off the Levantine coast. As there were no wild cats endemic to the island, there can be no doubt that people introduced cats to Cyprus as early as the Late PPNA, 9,000–8,600 cal BC.

Why did the earliest cultivators in the world undertake risky sea voyages together with cats, which were still very large, like the wild cats and potentially aggressive, although captive or tamed? It would seem that they were needed to control mice. Small mammal analyses show that commensal mice (*Mus musculus* ssp. *domesticus*) invaded the Levantine human settlements as soon as people started to accumulate cereals and legumes in the earliest sedentary Natoufian

hamlets. Zooarchaeological investigations also indicate that wild cats (and other small carnivores such as fox) became more abundant in the archaeological record starting from the PPNA, when the cultivation of wheat (see WHEAT) began (Vigne 2014).

Interestingly, a parallel but totally independent process has been recently described from the north China Neolithic. Remains of leopard cats (*Prionailurus bengalensis*), which were very frequent in this area, and which behaves the same way and occupies the same ecological niche as *F. s. lybica*, were frequently found in the Yellow River Neolithic villages. Some of them comprise skeletons deposited in graves. Some others show exceptional tooth wear suggesting extreme old age which is uncommon in the wild. All of these examples are slightly smaller than the wild form (Vigne et al. 2016). The leopard cat was therefore involved in an incipient domestication process. It seems that it was subsequently replaced by the western domestic cat descending from *F. s. lybica*, since all the domestic cats now present in China are genetically related to the latter.

Thus, in at least three different areas in the Old World, wild small felids were attracted by the proliferation of rodents resulting from early food storage and refuse accumulation. They became commensal and people are likely to have favored this natural process in order to control rodent pests or even because they wanted pets (Vigne 2014). Whether the Levantine or the Egyptian domestication gave birth to the modern domestic cat lineages is still unknown.

Contrary to dogs, small felids are naturally less variable because their morphology and behaviors are strongly constrained by their adaptation to the very specialized activity of hunting small mammals and birds. As this capability was the main reason why cats were domesticated, their morphology has remained largely unchanged since initial domestication. Diversity in form and shape dates principally from the start of the twentieth century when humans developed the pedigree breeds, including Bengal cats, which result from the hybridization between western domestic cats and wild Chinese leopard cats.

Dairying

ROSALIND E. GILLIS

Muséum national d'Histoire naturelle, CNRS (InEE),
France

The management of animals for dairy and the processing of dairy products are important industries in present-day societies and milk and its products make up a large component of the global diet. There are three main dairy species: sheep (*Ovis aries*), goat (*Capra hircus*), and cattle (*Bos taurus*). In Europe, cattle dominate dairy production particularly in northern countries, whereas across the Mediterranean basin and in the Balkan regions sheep and goat play important roles in providing milk and meat for pastoral communities. In addition, there are several other domesticated ungulates that are used as dairy animals across the world: the horse (*Equus caballus*, Central Asia), the donkey (*Equus asinus*, Africa), the one-humped dromedary camel (*Camelus dromedaries*, Middle East and Horn of Africa), the two-humped Bactrian camel (*C. bactrianus*, Central Asia), the yak (*Bos grunniens*, Himalayan Plateau), the water buffalo (*Bubalus bubalis*, South and Southeast Asia), and, to a lesser extent, the reindeer (*Rangifer tarandus*, Arctic Circle). These animals, together with the three main dairy species, are exploited for milk products that are transformed into different food staples. For example, horse milking has been practiced in central Asia since prehistory (3500 BC; Outram et al. 2009), and mare's milk is the basis of koumiss, a popular alcoholic drink, whereas yaks are concentrated mainly in the Tibetan plateau and produce rich milk, high in fat content, which is then made into butter, a food staple of the region.

Dairying provides a source of foodstuff that can be transformed into storable products that can act as a buffer for poor harvests and during periods in the annual season when food may be scarce. However, the ability to digest milk varies across populations. Lactose is the sugar within milk and, to digest this sugar, the body needs

to produce the enzyme lactase. The phenotype called lactose intolerance is in 65 percent of the global population; the remaining 35 percent have the phenotype called lactase persistence. The production of lactase is switched off in humans after they are weaned. However, in certain populations a mutation has occurred in the genetic code that allows for the production of this enzyme to persist. In Europe, the genetic mutation associated with lactase persistence is -13, 910T. The lowest frequency of this allele is in southeastern Europe; by contrast, the highest frequency is in northwestern Europe, where it reaches 95 percent (Itan et al. 2010). It has been proposed that there is a close relationship between the distribution of the allele and the development of dairy practices (Holden and Mace 1997).

The ejection of milk from the lumen to the teat cisterns is stimulated by the hormone oxytocin, which is important before and after parturition, for maternal behavior and bonding, and for milk ejection and letdown. Its production in the pituitary gland is stimulated by the sensory and tactile stimulus of the young, or through artificial means. Species vary in their ability to let down milk in the infant's absence; and phenotypic characteristics such as milk production are more plastic in some species than in others. For example, the letdown of traditional breeds of cattle is affected by the loss of the calf (see Figure 1). Therefore it has been proposed that early domesticated cattle would have required to be stimulated either by the physical presence of the calf or through artificial means, for instance by blowing into the cow's anus or vagina. Goats, on the other hand, are generally unaffected by the removal of the kid; and, to a lesser extent, sheep exhibit a similar behavior. The initial adoption of a particular dairy species would have been related to availability and to environmental tolerance or adaptability. Alongside other factors such as climate, cultural preferences may also have played a role in the development of husbandry practices and in the type of dairy products created.

The debate surrounding the evolution of European Neolithic dairying practices began

with the publication of Sherratt's (1981) theory of a "secondary products revolution," where "secondary products" refers to renewable products such as milk, wool, and labor. Sherratt's initial hypothesis was that dairying evolved alongside the Near Eastern early state societies of the fourth millennium BC, primarily for the reasons that early domesticates had poor letdown and human populations were lactose-intolerant. Advances in the organic residue analysis of ceramics (see *FOOD RESIDUE ANALYSIS*) have changed our understanding of the role of milk in early Neolithic cultures (Evershed et al. 2008). Large-scale analyses of ceramics from Neolithic contexts across Europe have shown that by the seventh millennium BC people were already processing and consuming milk (Debono Spiteri et al. 2016). In relation to lactose intolerance, the presence of dairy residues in pots indicates that processing techniques were employed to reduce the lactose content, as the sugar breaks down during cooking and fermenting.

Reconstructing dairy husbandry relies on the detection of the age and sex of animals in the zooarchaeological record (see *ZOOARCHAEOLOGY*). Sexing animal remains is hampered by butchery and taphonomic processes: these led to the destruction of whole elements needed for sexing, such as metapodials and pelvises. Ancient DNA has been used to sex elements and to deal with these data in conjunction with standard age-at-death analysis (see *ZOOARCHAEOLOGY AND ANCIENT DNA*). Animals' age at death can be determined from dental eruption, wear, and replacement and from postcranial fusion. The latter method provides large age

groups, and the results cannot be refined to allow the detection of subtle differences in slaughter practices associated with dairy husbandry. Thus, in general, zooarchaeologists use the age at death derived from the state of dental eruption, replacement, and wear. The frequencies from this analysis are presented mainly as triangular diagrams, survivorship curves, or histograms.

To interpret mortality profiles, models of subsistence dairy practices have been proposed on the basis of ethnographic observations (see Vigne and Helmer 2007). The development of models for interpreting mortality profiles is fraught with difficulties. Early domesticates are not comparable to modern breeds, which have been selectively bred for high milk yields. Furthermore, mixed subsistence practices would have been employed (rather than single-product systems). For example, Payne's (1973) initial models for milk, meat, and wool production for sheep have since been criticized for being unrealistic in relation to Neolithic husbandry practices, as they are based on those of Turkish market farmers. Further models of mixed husbandry practices have been proposed by Vigne and Helmer (2007) on the basis of ethnographic examples from subsistence farmers. For cattle, a postlactation slaughter model has been suggested, whereby calves are slaughtered after lactation, during weaning (Balasse and Tresset 2002). An intensive slaughter model for ancient dairying has also been proposed, whereby calves are slaughtered before the age of six months (Vigne and Helmer 2007). Milk letdown could have been maintained by artificial means and

through the sharing of calves. In marginal areas such as the Isles of Scotland, slaughtering one calf would have eased the pressure on fodder resources.

Along with mortality profiles, biomolecular analysis (see ZOOARCHAEOLOGY AND STABLE ISOTOPES) has aided our understanding of dairy practices. Measurements of $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ from collagen samples from the mandibular bone, where the dental eruption stage of the tooth adjacent to the bone sample is used as a time frame, can be employed to reconstruct the paleodietary history of cattle and thereby to provide an insight into weaning management practices. Values of $\delta^{18}\text{O}$ from incremental samples of enamel along the tooth axis can also be used to estimate the length of the birthing period (Balasse et al. 2012). Complementary stable isotopic analysis, in conjunction with mortality profiles, has been used to provide a detailed examination of herding practices during the Neolithic.

Recent pan-European projects (LeCHE FP7-ITN-215362-2; NeoMilk FP7-IDEAS-ERC/324202) have used multidisciplinary approaches to the understanding of the role of dairying in Neolithic societies and of how dairying has led to changes in human populations. At present, the picture that emerges is one of diversity. Ceramic vessels appear to have been used for processing dairy products from the beginning of pottery production as evident in the Sea of Marmara. This pattern varies for European Neolithic cultures, with strong evidence for dairying in western Mediterranean cultures such as Impressa and Cardial, but not in northern Greece. The correlation between high concentrations of milk lipids from pots around the Sea of Marmara and cattle, which dominate zooarchaeological assemblages, have led researchers to hypothesize that cattle played an important role in dairying. Early Neolithic cultures spread into central Europe, possibly following the riverine networks. Cattle played an important role in these communities, for example in the Linearbandkeramik culture. Therefore it has been proposed that dairying was an important food resource for these cultures. Analysis of ceramic sieves from the Polish site of Ludwinowo appears to confirm this hypothesis. The ongoing in-depth analysis of butchery practices and age at death, coupled with

organic residue analysis, indicates that the situation is more complex and fluid than previously believed. The production and consumption of dairy products would have been influenced by socioecological factors such as cultural tastes and the stocking capacity of a landscape for a herd of lactating animals. However, what is clear overall is that dairying was an important resource for Neolithic farmers and contributed to the expansion of Neolithic societies across Europe. Further research is needed to understand the evolution of dairying and dairy animals in other regions of the world.

Deep-Sea Fisheries

ALISON LOCKER

Independent Researcher, Andorra

Deep-sea fisheries, as currently defined by the Food and Agriculture Organization, operate at a depth ranging between 200 and 2,000 meters, “on continental slopes, oceanic seamounts, ridge systems banks” (Food and Agriculture Organization of the United Nations [FAO] 2010–18). Bottom-living and mid-water species are targeted through a range of gears such as “bottom and mid-water trawls, pots, and longlines” and the process “require[s] significant investment” (FAO 2010–18). However, when discussing deep-sea fisheries of the past, it is more relevant to describe them as offshore, as opposed to coastal or shore-line fishing (see FISH). Offshore fishing was, and continues to be, more risky than inshore fishing; especially in the age of sail, it was more exposed to changing weather conditions. The crews were far from their home port and vulnerable to disagreements over fishing rights. Fishermen also crossed open oceans, such as the Atlantic, to access distant fishing grounds and to bring the stored catch back to port at the end of the season.

This entry is written from a British and northern European viewpoint. The primary focus is on cod (*Gadus morhua* L.), the most commercial of the Gadidae, and on herring (*Clupea harengus* L.), a Clupeid. These two cold-water shoaling species have been the major targets of commercial fisheries from at least the late tenth century and until relatively recently. The history of both cod fisheries and herring fisheries demonstrates competitive fishing between nations, as demand grew with population growth and urbanization.

Many fish found in the deep sea are neither static nor restricted to that habitat. Migrations take place seasonally, for feeding and spawning. Fish often remain in discreet breeding groups and follow the same route each year. Immature individuals tend to be found closer

inshore and move into deeper waters as they grow—a process known as recruitment. These movements are closely monitored by fishermen who determine the balance of maximum return and profit against risk in the open sea. Before mechanization, dependence on wind and the lack of refrigeration were significant factors limiting the distance and time required to deliver fresh fish to shore. Steam-powered vessels and icing at sea were not introduced until the nineteenth century; freezing at sea was first practiced in the 1920s. The very success of modern factory fishing vessels, which catch, process, and freeze fish on board, spending months at sea, has contributed to the serious depletion of fish stocks and to the decline of traditional fisheries.

Cod has long been prized for its flesh and for its oil, the latter concentrated in the liver. “Train oil” was initially used for dressing leather, for lighting, and, later, as a medicinal source of vitamins A and D. Cod can grow to well over one meter in length, in a variety of habitats in the North Atlantic and the Arctic, up to depths of 600 meters, forming schools 30–80 meters above the seabed. They have a preferred temperature of around 6°, which can go up to a maximum of 15°. Young fish are found closer inshore, as are adults during the winter months, to the south of their range. Cod gather on banks in order to feed; these uprisings in the seabed create an area of shallower, nutrient-rich waters. There are a number of fishing banks in the North Atlantic, the largest being the Grand Banks off Newfoundland, where the cold Labrador Current meets the warm Gulf Stream.

Cod fisheries had long been important off the Norwegian coast: air-dried cod was made in the Lofoten Islands as early as in the Viking period. The North Sea, Iceland, and, by the late fifteenth century, the Newfoundland Grand Bank waters successively became the focus of European cod fisheries, whose fishermen went there for the season. Such was the value of these waters that fishing rights became fiercely contested and politicized.

Cod were initially caught using single hooked and baited hand lines. In the postmedieval

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0158

period long lines were developed, each with many “snoods” (short lines with a baited hook) attached to the main line. Setting and hauling in long lines was very labor-intensive and not mechanized until the 1960s. In the nineteenth century the development of trawls maximized the return on cod catches. This accelerated overfishing, which had already impacted on what was often seen as a limitless supply. However, there were concerns, as indicated by the early legislation that protected freshwater fish populations and immature marine stocks.

The traditional “dogger,” an open rowing boat with sails used at least from the fourteenth century, was robust enough for the North Sea and Iceland seasons. For Newfoundland, bigger vessels were required, which carried larger crews and supplies across the Atlantic. Initially Breton and Basque fishermen made the journey; later on they were followed by other nations, the English joining relatively late. The fishery was the subject of much dispute and rivalry. These fisheries were not of the deepwater variety, as cod were caught in comparatively shallow waters, but fishermen crossed the Atlantic to reach them.

Cod bones are relatively uncommon in archaeological deposits before the tenth century AD, when the commercialization of the fishery took place, to meet the new demand from growing settlements (Barrett, Locker, and Roberts 2004). Large cod were found in some earlier Saxon monastic and “wic” (trading towns) contexts in the southeast of England and are thought to reflect high status.

Herring is a member of the Clupeidae, found north of 30° latitude, in both saline and brackish conditions. Tolerant of water temperatures up to 18° but preferring 8°, herring can be found at depths up to 364 m. They spawn over winter in shallow waters, but as adults they feed offshore. Averaging 30 cm in total length, they can be found in numbers of up to a billion in one single school (Lamichhaney et al. 2012). Discrete breeding groups have a specific annual migration route to their spawning grounds and can be distinguished by variations—for example, in the numbers of vertebrae (Hodgson 1957, 15) or in the size of the fish—and also by genome (Lamichhaney et al. 2012). In the North Sea there are three main groups: the Buchan, the Dogger, and the Downs groups. Buchan herring, the most

northerly, migrate first, then Dogger, and lastly Downs; this ensures that, although their routes overlap in part, they do not mix. At times herring are close inshore and young fish enter estuaries, being netted in large numbers by local fisheries and become increasingly common in archaeological deposits at larger settlements from the Roman period onward. The commercialization of the fishery is evident from the late tenth century AD: herring bones are often the most numerous specimens identified by species in archaeological deposits from this period (see FISH; Barrett, Locker, and Roberts 2004).

The history of the herring fisheries was as politically charged as that of cod fisheries and was vulnerable to boom and bust, as fish numbers fluctuated. These oily fish soon became rancid and, prior to refrigeration, much of the catch was cured. In Britain, the North Sea fisheries were centered around East Anglian ports, where fresh, salted, and pickled fish were an important trade, hard-smoked “reds” being produced from the fourteenth century. The Dutch were soon dominant in the fishery and nations competed at developing new curing methods in order to capture this lucrative market.

Herring are netted with seines and gill nets; originally this operation was conducted from small open rowing boats, but, as the industry grew, the boats and the crews became larger. The shallow-bottomed boats were used in inshore waters by the Dutch to land their catch in drift nets. These were superseded by Dutch “busses,” an early factory ship that soon dominated the North Sea herring industry.

The archaeological evidence for these fisheries consists primarily in the bones recovered during excavation (see ZOOARCHAEOLOGY). Fishhooks and weights have also been found but are difficult to attribute to specific fisheries. The location and contextual date of fish bones show growth in the market that delivered cod and herring through time and space. Quantitative methods suggest when and where cod overtook herring as the prime commercial species.

Analyses of anatomical distributions have revealed “bone signatures.” The disproportionate representation of different parts of the skeleton can indicate whether cod bones were from fresh or from stored fish, as certain elements are

removed through salting and drying. Bone measurements can determine the size of individual cod; a particular range was considered best for storage (Barrett, Nicholson, and Ceron-Carrasco 1999; Hamilton-Dyer 1995). Even in a small fish like herring, processing methods can be observed from bone distributions. A specific gutting method was observed in a deposit in Denmark with bones predominantly from the throat area (Enghoff 1996).

The analyses of isotopic elements from individual cod bones recovered through excavation have been used to indicate the origin of these bones (see ZOOARCHAEOLOGY AND STABLE ISOTOPES). Stable carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) have a signature, determined by environmental factors attributable to a region (Barrett et al. 2008). The results reflect the expansion of cod fisheries designed to supply the market from the North Sea, the Baltic, Iceland, and ultimately Newfoundland.

Although much on the development of fisheries can be ascertained from documentary data, the zooarchaeological bone evidence has proved to be a crucial part of ongoing multidisciplinary projects that engage fish scientists and historians. The archaeological bone evidence has added new data for periods predating the collection of fisheries statistics; previously these statistics were used as a baseline in determining overfishing. The inclusion of bone data and of other evidence—such as early testimonies on bottom trawling before the first statistics taken in 1886 in the United Kingdom (Thurstan, Hawkins, and Roberts 2013)—has shown that overfishing was a problem well before these records began.

On-site sampling and sieving of deposits secures the recovery of the smallest fish bones (see SAMPLING IN ENVIRONMENTAL STUDIES). These have provided a database for meta-analyses of large groups of data that show trends in fish consumption, and therefore in fishing. The application of genetic and isotopic analytical techniques on cod bones in particular is a developing field and an important element in refining the history of fish stocks, in fisheries science, and in the development of proto deepwater fisheries.

Desert Environments

SAVINO DI LERNIA

Sapienza University of Rome, Italy; GAES, University of the Witwatersrand, South Africa

The word “desert” comes from the Latin verb *deserere*—to abandon—so *desertum* means “abandoned.” In its very etymology, this word thus contains the notion of the temporal process that produced it: in other words, a desert is a place that was once inhabited. For this reason, desert environments play a fundamental role in the archaeological sciences as privileged locations for analysing the interface(s) between climate, landscape, resources, and humans.

Research on desert areas is particularly important when we consider the process of desertification, of enormous significance in the contemporary world. Desertification, that is the spread of deserts encroaching on more vegetation-rich lands, is triggered by both natural and anthropic factors. Today the study of past desertification can provide significant insights of help in combatting this process, which seriously affects large parts of the planet, including the use of traditional systems for managing land, water, and resources. There is no “official” definition of the term desert, so we refer here to landscapes currently characterized by scarce rainfall (under 250 mm per year according to Köppen’s 1918 climate classification), high temperature oscillations and sparse (or no) plant cover. This harsh climate type affects substantial areas of the planet (roughly a fifth of the earth’s land surface). The Arctic and Antarctic Polar Deserts are the largest cold deserts on Earth, whereas hot deserts are mostly located at lower latitudes. Desert environments are present in all continents, with different locational and physiographical features that may greatly influence the human presence. Despite their harsh environment, deserts are home to an astonishing biological and cultural diversity. Today, over one billion people live in deserts, mostly concentrated in towns and villages with vast areas where humans are virtually absent.

The Sahara, with a surface area of over 9 million km² (3.5 million square miles)—approximately a third of Africa—is the world’s largest hot desert. Located in the northern part of the continent, the Sahara presents highly diverse geographical, geological, and physiographical features. Stretching from the tropics in the south to the Mediterranean Sea in the north, and from the Atlantic in the west to the Red Sea in the east, it can be considered with some caveats a valid representative of desert environments. Although the iconic image of the Sahara Desert is that of large dune fields (*erg*, or *edeyen* in Arabic), it mostly consists of a flat, barren pavement covered with small rocks and pebbles, locally known as *reg* or *serir*. Except for the Nile, there are no permanent water courses. Former river systems (see RIVER SYSTEMS), now extinct or seasonally reactivated by occasional rains, are known as *wadis* and in several cases host large oases. A long tradition of environmental, archaeological, and rock art research beginning in the mid-nineteenth century has made the Sahara particularly rich in scientific data.

Given the scarce human presence, mostly restricted to oases and modern villages, anthropic pressures on desert environments in historical times—except for development and infrastructure projects—have been much less aggressive than in other biomes. This has helped, at least in part, to better preserve the archaeological landscape. Archaeological survey—by foot, camel, 4X4 vehicles and now drone-assisted flight recording—is a key method for identifying evidence of a past human presence (see FIELD SURVEY). Although this evidence varies from isolated scatters of stone tools to the remains of underground water channels, much scientific research in the Sahara has consisted of large-scale, extensive surveys (Kuper and Kröpelin 2006), with excavation being far more limited (Wendorf and Schild 2001).

More recently, the combination of remote sensing analysis of satellite imagery and the use of digital devices in the field has improved our ability to identify, map, and record archaeological sites in

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0219

arid lands. Given the nature of the terrain and the peculiar physiography of desert landscapes where vegetation is virtually absent, we can distinguish between different types of locational context, each with a specific capacity to attract a human presence and preserve the archaeological record, and with its own degree of archaeological visibility.

Open-air contexts mainly consist of scatters of archaeological materials (lithics, pottery, bones, grinding equipment, etc.) and remains of stone structures (fireplaces, huts, walls, ritual/funerary structures, geoglyphs, etc.). Their state of preservation varies dramatically, as does their archaeological visibility. In some cases, erosional processes in desert environments create stone-line features consisting of an accumulation of dismantled archaeological layers, of extremely high density. Here, statistical methods of spatial analysis and sampling may greatly enhance our understanding of past human occupation(s). From a stratigraphic point of view, negative features normally prevail over positive ones and multilayered, stratified contexts are rare. Among the exceptional examples of good preservation, are the Early to Middle Holocene cemetery of Gobero, Niger, and some sites around Nabta Playa in Egypt. Both, however, are characterized by the presence of lacustrine sediments covering and partially protecting the archaeological features. Stone structures, particularly those with a funerary/ritual purpose, are of crucial importance for the study of Holocene populations, especially after the onset of desert conditions around 5,900 years ago (Tierney and deMenocal 2013). Sometimes these stone covers are the only protection against wind erosion, a major geomorphological agent in desert environments. For this reason, much archaeological research in the Sahara has focused on stone monuments, giving rise to an important tradition of studying ritual customs, funerary practices, and bioarchaeology (see BIOARCHAEOLOGY). Rock art sites (mostly graffiti and engravings on isolated boulders, cliffs, and rock walls) are another important segment of the desert's archaeological landscape. Their preservation is greatly endangered, not only by environmental pressures but also by a variety of anthropic threats.

Sheltered contexts, like caves, rock shelters, niches, and alcoves (see CAVES AND FISSURES), have been intensively used by human groups and

are still frequented by nomadic herders across the Sahara such as the Tuareg and Tebou. Their archaeological visibility is excellent on the ground making them easy to target during field surveys but much less so through remote sensing. Given their natural protection from wind, rainfall, and sunlight, the preservation of archaeological deposits is better than in open-air contexts, with some extraordinary instances from different parts of the Sahara. Arid conditions prevented bacterial activity, significantly favouring the preservation of organic remains, including fruits, seeds, and other plant macroremains. Pollen analysis (see PALYNOLOGY) and archaeobotanical studies (see PALEOETHNOBOTANY) can therefore be used to enhance our understanding of past climate and environmental variations in these landscapes, as well as the human exploitation of plants for food and fodder. Additionally, the repeated use of these places has created true palimpsests with complex stratigraphic sequences, as is evident in the central Sahara (Biagetti and di Lernia 2013). In these contexts, dung represents a specific type of archaeological deposit with extraordinary potential for defining and understanding ancient herding strategies (see COPROLITES). Shelters help to preserve artworks such as pictograms, engravings, and other markings. Caves and shelters may also preserve human burials—normally of the Holocene period—with exceptional instances such as the naturally desiccated bodies of several humans found in different parts of the Sahara including Ti-n-Hanakaten (Algeria), and Uan Muhuggiag and Takarkori (Libya).

The differing state of preservation of these diverse contexts may affect our capacity to date the principal environmental and cultural phenomena correctly. This is particularly important for research on the timing and dynamics of desert formation, and the adaptive mechanisms developed by past human groups. Climate studies have a privileged position in desert environments, which should be considered true laboratories for analysing the relationship between humans and the environment. Significant advances in the field of climate change and climate modeling have been made thanks to research in the Sahara, in particular its central and eastern regions. Geomorphological studies of ancient lacustrine sediments and palaeo-shores, and core drillings of surviving lakes, have greatly expanded our

knowledge of the Pleistocene and Holocene climate variations (Kuper and Kröpelin 2006; Drake et al. 2011), providing crucial information for defining the so-called “African Humid Period.”

OSL, TL, and radiocarbon datings are routinely used to date ancient landforms, archaeological contexts, and rock art sites (see DATING IN ARCHAEOLOGY). A particular tool is the patina known as “desert varnish,” usually a dark coating consisting of different minerals and manganese covering open-air rock forms, sometimes including rock-art panels and stone features. Its chemical composition, color, and inner microstratigraphy may provide a wealth of information on past environmental variations. Furthermore, the organic particles trapped in the coating can be AMS radiocarbon dated, providing a *terminus ante quem* for the object investigated. Studies of desert varnish are common worldwide, with significant traditions in North America and the Sahara (Dorn 2007).

In desert environments, oases are crucial hotspots for plant and animal life, including humans. In the Sahara, the oases formed in the Late Holocene and hosted the first sedentary communities. In these areas, the archaeological record may consist of villages, hamlets, and towns. Monumental tombs and infrastructure—such as *fogārah* (underground water capture systems)—also punctuate specific segments of the landscape (slopes, wadis, etc.). Although oasis formation is a natural process, its maintenance and development is due to the human intellect and their painstaking efforts. The exploitation of water and the capacity to cultivate these regions are evidence of the extraordinary human ability to adapt to harsh environments. In preindustrial times and sometimes even today the only access to water consists of rock cavities filled by occasional rainfall. Called *gueltas* in Arabic, these features are of the utmost importance for nomads now living in the desert, and the same was true in the past. Many *gueltas* are historiated by artworks, engravings, rock markings, and inscriptions, sometimes thousands of years old.

By definition, food resources in desert environments are scarce and unevenly distributed. Seasonal gathering is restricted to a few watered areas, such as the *gueltas* of protected wadi systems. Cultivation is limited to the oases, where cereals and other pulses are grown thanks to

springs and wells. Traditional wells (*bir* in Arabic) normally exploit very low water tables, whereas deep wells (mechanically built with electric or motor pumps) may use fossil water and thus favor industrial-type production. Flood-recession cultivation is a traditional form of farming using temporary ponds, known in the Sahara as *etaghas*, *tesahaq*, or *tmed*. The geomorphological features of these ponds allow for occasional cultivation after heavy rainfall: their flat surfaces and more limited exposure to wind and sun mean that they retain water for longer. Research in the central Sahara suggests that this traditional farming method may date back at least to pre-Islamic times. Archaeological evidence around these ponds consists of small campsites, farming facilities (walls, ditches, fences, stone markers), a few artifacts (potsherds, grinding stones, and lithic tools) and rock-art markings.

Given the decline in wild fauna, hunting is currently little practiced although poaching unfortunately still occurs. Herding is the best form of subsistence adaptation to desert environments, especially when practiced on a year-round nomadic scale that prevents overgrazing and the deterioration of pasture and water resources. In Africa, and in the Sahara in particular, pastoralism is a very ancient form of subsistence, dating back to the Early Holocene and preceding agriculture by thousands of years (Marshall and Hildebrand 2002). The archaeological reconstruction of herding is based on the study of settlement organization, investigation of faunal remains (see ZOOARCHAEOLOGY), identification of milking through pottery residues, analysis of coprolites and spherulites, and the recording and interpretation of artworks. The combination of archaeological data and spatial analysis of settlements is of the utmost importance. Ethnographic evidence and ethnoarchaeological analysis can greatly improve our capacity to reconstruct past pastoral systems.

Given their natural constraints, large areas of desert environments are barely populated. Yet various human groups chose, or were forced to choose, these places for maintaining their traditional lifestyles. This is true of the nomadic herders of the Sahara, but also for example of the San hunter-gatherers of the Kalahari in southern Africa or the Aborigines of Australia's desert outback. The ethnoarchaeological study of these groups is crucial for understanding

the mechanisms of adaptation(s) to these harsh environments. Since the 1950s, such studies have been fundamental for theory building and contributed significantly to the emergence of processual and, later, post-processual archaeology (David and Kramer 2001).

Despite the physiographic and environmental limitations, deserts have hosted great ancient societies. In the Sahara we have not only the extraordinary case of Ancient Egypt (although the presence of the Nile significantly influenced the environmental context), but also the emergence of the Garamantian state in the very heart of the desert. The mechanisms of settlement coagulation and political control in such environments have been thoroughly investigated by different teams bringing a different, and fresher, perspective to the theoretical debate on state formation and development (Mattingly et al. 2006).

The natural and cultural heritage of desert environments is seriously endangered (see HERITAGE AND LANDSCAPES). Environmental threats mostly result from the very nature of these regions: high temperatures, strong temperature oscillations, wind erosion. Anthropogenic threats are also very serious. Infrastructure building, underground exploitation, development, poaching, illicit trafficking, agricultural reclamations, and tourism are just some of the pressures that humans exert on this incredibly fragile heritage. Unlike wind erosion and thermoclastism, however, these threats can be mitigated. Plans for conservation and raising awareness of the need to preserve these environments are among the main aims of United Nations organizations and numerous NGOs, and also involve the local communities, the guardians of these extraordinary regions (Goudie and Seely 2011).

Diatoms

NIGEL CAMERON

University College London, UK

Diatoms are a very diverse and distinctive group of single-celled algae that are abundant in aquatic habitats. The silica valves enclosing diatom cells are taxon specific and are commonly preserved in aquatic sediments. These features, along with the sensitivity of diatoms to many aspects of water quality, led to their value in archaeological investigations.

An early application of diatom analysis to archaeological questions was during the 1940s in studies of prehistoric settlement along the changing shorelines of the Baltic Sea. The sensitivity of diatoms to salinity and the preservation of diatom sequences in the sediments of lakes isolated from the sea enabled the reconstruction of former sea levels and the prediction of former settlement locations through different phases of isostatic land uplift and eustatic sea-level change (see SEA-LEVEL CHANGE).

Diatom-based environmental reconstruction in coastal and estuarine archaeology is an important part of multiproxy paleoenvironmental studies (Sidell et al. 2000). In tidal habitats it is important to take account of autochthonous and allochthonous components of the diatom assemblages. It has become more common to use multivariate techniques to calibrate modern diatom communities with contemporary water chemistry and apply such models to fossil diatom assemblages in sediments of archaeological interest. For example, this has allowed the relationship of historic and prehistoric sites in London to be related to the changing nature of the River Thames. Other archaeological studies involving diatom analysis have shown the effects of both salinity change and anthropogenic nutrient enrichment (see WATER POLLUTION), for example in the fortified Roman town of Leiden in the Netherlands (Brandenburgh and de Bruin 2016)

and in the recent past in the vicinity of whaling settlements in the Arctic (Douglas et al. 2004).

The presence of diatoms in both contemporary and fossil clay sediments used in the manufacture of artifacts has led to the application of diatom analysis in studies of clay provenance and typology. These studies are exemplified by work on ceramics particularly of ancient material, where firing temperatures were low enough to allow the survival of diatom silica. In addition, investigations of diatomaceous clay bricks used in construction in ancient Egypt have been used to characterize the mud bricks (see ADOBE) and potentially to correlate bricks within and between monuments (Flower 2006). There have also been attempts to investigate past river water quality and clay provenance in the Middle East through the identification of diatoms preserved in dated clay tablets on which agricultural inventories were recorded in cuneiform script.

The presence of diatoms within internal organs can be used in the diagnosis of drowning. This diatom test for drowning, usually applied to assist pathologists in forensic investigations, has been employed at a Late Neolithic site in Sweden. Diatoms extracted from within human long bones were found to be similar to the diatom assemblages of sediment in a well. In combination with other archaeological evidence, this led to the suggestion of ritual killing (Carlie et al. 2014). Diatom analysis has also been applied to the investigation of the source of materials associated with ancient burials.

Diatom analysis is commonly used in the study of ancient boats. Both inland and seagoing vessels from the Bronze Age to the Medieval have been subject to diatom analysis. These studies have involved examination of the context of the boats, and sediments on which they came to rest. In addition, boat planks, caulking material such as moss, and other artifacts associated with submerged wrecks have been investigated by diatom analysis to assist in determining the range of environments in which the boats were used. The aquatic environments of several waterfront and harbor sites in northern

Europe and in the Mediterranean have also been investigated through diatom analysis, often in conjunction with foraminifera analysis (see FORAMINIFERA).

The use of geological diatom deposits with a high diatom content, deposits known as diatomite, provide a means of tracing the exploitation and trading of materials. Diatomite may have been deliberately used in manufacture or may contaminate artifacts.

Archaeological features such as cave sediments, wells, pits, post holes, and sediments around fish traps have been analyzed for diatoms to investigate local environments. Diatom analysis has been used in experimental archaeology to assist soil micromorphological interpretation of habitation floor layers where the drinking habits of livestock can be examined through the excretion deposits of diatom valves (see MICROMORPHOLOGY).

Diatom analysis of settlements built next to lakes, rivers, and channels has been used in multiproxy investigations particularly in northwest Europe. Examples of these settlements are the humanly constructed islands known as crannogs that supported buildings constructed in lakes and in sea lochs. The majority of crannogs constructed in Scotland, for example, date from approximately 800 BCE to 200 CE, although crannogs there and elsewhere exist from outside this age range. In the vicinity of these, other lake and riverside structures, and also moats and fishponds associated with medieval buildings, diatoms have shown evidence for eutrophication and aquatic habitat changes (e.g., Keevill 2004). These can be attributed to the nutrient inputs from the settlements and associated agriculture. At other sites, using diatom analysis, the freshwater nature of the settlement environment has been established following phases of marine regression.

Disaster Archaeology

RACHEL EGAN and PAYSON SHEETS

University of Colorado Boulder, USA

Scholars and the general public have long been fascinated by ancient disasters. Disasters have played major roles in human history, beginning with volcanoes affecting our ancestors in East Africa 3.6 million years ago (Oppenheimer 2011). The interest in nature's extreme events, such as volcanic eruptions (see ARCHAEOLOGICAL VOLCANOLOGY), earthquakes (see ARCHAEOSEISMOLOGY), droughts, and floods (see FLOODING), lies in their ability to produce an array of dramatic responses, including the collapse of societies or cities, of which the destruction of Pompeii by Vesuvius is the best known case. However, much of the literature on disasters is unilinear: A impacts B, disaster strikes, and the society suffers. This cause and effect paradigm emphasizes those most drastically affected. This directed emphasis is exemplified by the media, where the focus is always on the loci of greatest destruction for present day disasters, then quickly moving onto other topics, leaving long-term recovery and adjustments virtually untouched. Scholarship similarly has emphasized the immediacy of impacts. Only recently have archaeologists considered long-term recovery processes within social contexts (Torrence and Grattan 2002).

The study of disasters, perception of risk, and mitigation, have been dominated by the natural sciences and engineering (Riede 2015). The term "natural disaster" is an unfortunate reflection of that domination. However, there is a growing realization that social processes are fundamental components of disasters. Therefore understanding the cultural and social factors are at least as important as the natural forcing mechanisms. Just as a disease reveals to the physician the workings of the body, so to the social scientist the disaster reveals the working of the affected society. Recent decades have witnessed the emergence of social science studies of these topics.

While social scientists focus on the immediacies of risk, vulnerability, and mitigation of societies today, almost entirely in developed countries, anthropologists and archaeologists study disasters and their components around the world and over long timespans. The realization that the historical contexts that precede and follow a disaster are necessary for understanding an event has uniquely qualified archaeologists to study the long-term recoveries and adjustments made by societies. Further, archaeologists study the full range of societies, from hunting and gathering and horticultural egalitarian groups through chiefdoms and into stratified states and empires, providing a more comprehensive approach. By investigating societies prior to the disaster, the impacts of the event, and the long-term aftermath, scholars are discovering the complex ways in which vulnerabilities are produced.

The natural forcing mechanisms vary considerably around the world, summarized by Mauch and Pfister (2009). They include floods, droughts, summer frosts killing crops, earthquakes, volcanoes, famines, diseases, forest fires, and storms. A human universal is the need to explain the workings of their environment, and extreme events are regularly seen by traditional societies as sent by the supernatural domain, often interpreted as a result of human misbehavior (Krajick 2005). The cases examined often included progressive learning embedded in disaster responses, as societies that have learned how to ameliorate the negative impacts of future events. Traditional societies often embed quite rational behavior into their oral histories or religions, thus mitigating the impact of the next disaster. Native American societies along the Pacific Northwest Coast knew that the clash of the Whale sea deity with the Thunderbird sky deity creates an earthquake and perhaps a tsunami, so they mitigated risk by heading inland. Current residents of Seattle are less prepared for the next tsunami than were Native Americans. After the huge 2004 earthquake in Southeast Asia, the traditional Moken people perceived the ocean receding from their fishing villages, so they headed out to sea, and

DOI: 10.1002/9781119188230.saseas0192

the tsunami wave passed under them with no difficulty. Over a quarter million more “modern” people living in coastal areas, but devoid of the traditional knowledge, were killed when the tsunami crashed into their shores.

Many disasters were interpreted as divine retribution for human misbehavior. When the Maya skybearer deities perceived significant human misbehavior, they stomped their feet, creating an earthquake, and then religious specialists interpreted the event and acted to change human behavior. In other cases, elites and royals claimed enhanced connectivity with the supernatural domain and thus had primary responsibility for the functioning of society. When functioning fails under a disaster, confidence can be lost and as a result religious-political upheaval or revolt can ensue, as exemplified by the Chinese emperor losing the mandate of heaven in the wake of a particularly severe drought in the mid-sixth century (Gunn 2000).

Societies that have faced recurrent disasters often develop cultures of coping, which can involve quite rational behavior, along with religious belief and psychological adjustment. Although their explanations differ fundamentally from our scientific explanations, societies affected by great geophysical stresses can learn from them, embed the knowledge in oral history and religious belief, encode emergency behavior, and thus provide resilience to future events.

Archaeologists have recorded different volcanic impacts on a wide range of societies around the world (see *ARCHAEOLOGICAL VOLCANOLOGY*). In spite of all the variability, comparative analyses are discovering some common patterns (Sheets 2001). Although it may seem counter-intuitive, “simpler” egalitarian societies often fared better than more complex societies when impacted by explosive eruptions depositing thick layers of volcanic ash across their landscapes. For instance, horticulturalists in the Arenal area of Costa Rica were impacted by 10 big eruptions of the Arenal Volcano in the past 4,000 years. The villagers fled to viable refuge areas, waited for a decade or two for ecologic recovery, and then resettled their original villages. The key factors in their resilience were small villages (a hundred people or less), low regional population densities, lack of warfare, available refuge areas, and food from domesticated plants and the biodiversity of

the tropical rainforest. Their recoveries probably were aided by oral histories. A different aspect of these villagers is presented toward the end of this entry.

The chiefdoms in nearby ancient Panama were similar to the Arenal villagers in many ways, but their social differences resulted in greater vulnerability to volcanic stresses (Sheets 2001). The chiefdoms engaged in capture warfare, and the landscape was more densely populated to provide more warriors. Each chiefdom had one or two thousand people. Although they functioned well for many centuries, they were on the threshold of sustainability. When the nearby Baru volcano erupted with a moderate-size explosion, people had to relocate and never returned. Although the eruption was smaller than all 10 of Arenal’s eruptions, the Panamanian chiefdoms had less resilience to the unanticipated stress and had no nearby refuge area because of warfare. They were therefore more vulnerable and the chiefdoms collapsed.

The state level societies of Mesoamerica, with their greater population densities and accentuated social differentiations among classes far greater than chiefdoms, were often highly vulnerable to natural stresses. For instance, Teotihuacan was the greatest city of Mesoamerica in the first half of the first millennium AD, powerfully influencing surrounding societies for hundreds of miles by their extensive trade network and compelling religion (Oppenheimer 2011). Over 100,000 people lived in this highland city, at some 7,000 ft in elevation, and thus close to the frost line. The climate was semiarid, so in years with average temperatures and rainfall on the corn, beans, and squash triad of crops grown would provide food for all. A bad year due to drought or frost could be tolerated by storage and exchange; however, their resiliency was greatly exceeded by the decadal-long drought and frosts that began in AD 536. In the years following the commoners rebelled against the elites, selectively burning elite temples and compounds as well as smashing the sculptures of the water deity, culminating in collapse.

The cause of this particular stress was unknown until recently. The cataclysmic eruption of Ilopango volcano, El Salvador, in AD 539 was the major player in causing a worldwide cooling and drought that lasted for over a decade (Oppenheimer 2011). Teotihuacan suffered the

distal effects of the eruption, as did so many other societies inhabiting marginally productive areas. The Maya living within a 100 mile radius of the volcano suffered the proximal effects: all people, animals, plants, fish, and other living things were completely eliminated in what is now El Salvador, and into adjoining countries. This was a complete cultural-natural disaster, as there were no survivors to initiate recovery, and the people who eventually recolonized the area were quite different.

Other volcanic eruptions in Mexico and Central America, as well as other parts of the world (Oppenheimer 2011) have caused varying degrees of stress on societies, and many of them recovered and often found new ways of coping with volcanic hazards. An example is provided by the villagers near Arenal volcano (Sheets 2001), where multiple eruptions affected small horticultural villages in the tropical rainforest. From about 500 BC to AD 600 individual villages acting independently abandoned their settlements and took refuge until ecologic recovery occurred. The villagers reestablished residence in their original villages and resumed single-file pilgrimages to their cemeteries, often located at considerable distances. At about AD 600 they established a shared cemetery, and it was shared by at least one village eastward toward the volcano, and at least one village westward on the dry Pacific drainage. Villages were much too small to have been endogamous, so marriages must have occurred outside of each village. The alliances and intermarriages that must have occurred formed relationships that could be used for refuge by the volcanic-impacted villagers. And when drought affected the western villagers, they could take refuge in the wetter tropical rainforest near the volcano, with its great biodiversity and biomass of edible foods. Eruptions were of such frequency, averaging one big one every four centuries, and many smaller ones, that villagers must have maintained an oral history of precursors, eruptions, and mitigating behaviors. Establishing a shared cemetery and the alliances that ensued provided refuge for the villagers struck by the eruptions, and provided food for the easterners when drought struck. This appears to have been a sophisticated example of risk management. Unfortunately, European-introduced diseases completely depopulated native villagers

in the area, with the Spanish Conquest, thus eliminating whatever oral history and traditional environmental knowledge had been achieved. When modern Costa Ricans settled the area in the twentieth century they were unaware of the hazard, did not know how to act when the precursors of the 1968 eruption occurred, and many perished. Mauch and Pfister (2009) cite other cases where colonization or modernization decreased resilience to disasters.

Natural and cultural components of extreme events have been, and continue to be inextricably intertwined, and they can take place over a long time. Only by incorporating the histories that precede and follow the manifestation of an event as well as the differential way that these events can impact society, can we begin to reconstruct past disasters. Disasters are now being studied by many archaeologists, often in large multidisciplinary research programs. And as a result, our understanding of vulnerability, resilience, and recovery are becoming much more nuanced.

Domestication

TIM DENHAM

Australian National University, Australia

Domestication, like many other terms that have apparently straightforward meanings, is actually very hard to define. Within archaeology, meanings commonly range from socially oriented perspectives that emphasize domesticatory relationships of people with animals, plants, and places, to biologically oriented definitions that focus on the phenotypic and genotypic transformations in animals and plants as a result of human selection. There are also common misconceptions regarding domesticates, such as the requirement for human intervention in order for them to reproduce; such a definition would apply to only a handful of species in human history, most notably maize (*Zea mays*).

Taken at its most general, social domestication refers to the way in which things and places are brought into the human realm. Here there is no clear-cut demarcation of when domestication started because the processes involved are gradational, nonlinear, and multilayered. Effectively, domestication results from the intersection of a range of practices through which people intervene in the life cycle of animals and plants, as well as in the construction of place (principally at the landscape-scale). Further, the domestication of individual species is often entwined with “domestication” of the environment. Although proponents of more socially oriented definitions of domestication may lean on post-processual discourses, they often retain a teleological component; namely, the scale, directionality, and intensity of domesticatory relationships ratchet up through time.

For archaeologists, the domestication of animals and plants has primarily been empirically documented from morphological transformations in zooarchaeological (see ZOOARCHAEOLOGY) and archaeobotanical (see PALEOETHNOBOTANY) remains through time. As such, the archaeology of

domestication has been reliant on documenting phenotypic traits that are considered to characterize early stages in the domestication process and subsequent varietal differentiation. Using archaeobotanical and zooarchaeological methods alone, it was possible to document morphologically expressed phenotypic traits, such as nonshattering seeds and size reduction in animals, as opposed to behavioral traits that could not be directly observed in archaeologically preserved materials, such as photoperiod sensitivity in plants and sociality in animals. However, some morphological traits may not ordinarily preserve at archaeological sites—such as coat color and eye color in animals. In recent decades, aDNA has been used to identify population affinities and the emergence of genetic markers of specific traits associated with domestication, including a range of morphological and behavioral traits.

Two evolutionary processes have been heavily implicated in the domestication of animals and plants under human management: directed selection and genetic isolation (Larson et al. 2014). Directed selection refers to the advertent and inadvertent roles of humans in mediating the evolution of a species. Human-mediated selection can include spontaneous adaptations within anthropic environments (namely, the human niche), extensive land management and resource intensification practices, as well as intensive cultivation and husbandry. Genetic isolation refers to the limited ability of managed, cultivated, and husbanded animals and plants to interbreed with wild populations of the same or related species. Genetic isolation enables the accumulation of phenotypic and genotypic attributes within selected subpopulations relative to the parent population, namely, without continual dilution of selected traits resulting from interbreeding with wild populations. Genetic isolation is ordinarily achieved through moving a species outside of its natural range, as well as through the physical separation of managed from wild populations. Genetic isolation can also be effected by: the eradication of wild populations through environmental degradation and habitat

destruction, and through overhunting leading to local extirpation and extinction; the removal of pollinators through climatic, environmental, or anthropic processes; and, vegetative (clonal) reproduction of plants. The relative importance of directed selection and genetic isolation has varied for different animal–human and plant–human domesticatory relationships.

Domestication has been characterized as coevolutionary, namely a mutually beneficial relationship between people and a plant or animal. The mutual evolutionary benefit is demonstrated by the ability of a species to spread widely and outside its natural range, especially in comparison to ecological competitors. There are mutual influences for both parties within the domesticatory relationship, including the phenotypic (including behavioral) transformations to the animal or plant, and transformations to human behavior and social forms engendered by cultivation and husbandry.

Plants

The character of human–plant domesticatory relationships can be exemplified against a range of plant exploitation practices, including gathering to intensive cultivation. An increased intensity of human management, namely through levels of intervention in promoting the conditions for growth of plants, occurs as a result of tending and weeding, periodic pruning and burning to encourage new growth, as well as clearing of vegetation around stands of favored plants. Here, the level of human intervention in plant life cycles increases, with attendant human-directed selection of favored phenotypic traits among managed plants. The degrees to which these phenotypic preferences become more frequent within a population, as well as the degrees to which genetic markers of preferential selection practices become fixed, reflect numerous factors, including persistence of human practices and degree of interbreeding with populations not subject to the same degree of selective pressure. A stepped change in human-directed selection occurs with planting, including transplanting.

Domestication traits have been charted in archaeobotanical assemblages of cereals and legumes using grain size and prevalence of

nonshattering—many other phenotypic traits associated with domestication are not readily identifiable in the archaeological record (Table 1) (Fuller et al. 2014). Domestication as a process is considered directional and cumulative; namely, the relative frequencies of domesticated versus wild plants increase through time in archaeobotanical assemblages. The domestication episode refers to the period of directional change leading to “fixation” of a trait.

Animals

A wide range of animals have been domesticated by people, most notably mammals and birds, but also species as diverse as bees (*Apis* spp.) and silkworms (*Bombyx mori*). The domestication of mammals produced diverse phenotypic responses, including size reduction, cranial changes, horn-size reduction, coat color changes, decreased flight responses, increased sociality, earlier reproduction, and metabolic transformations, to name a few (Clutton-Brock 1999). People initially managed and domesticated animals for behavioral traits, with morphological transformations being a secondary outcome of management. The rationale and timings of animal domestication vary greatly across the globe.

Animals have been grouped according to three domestication pathways (Table 2) (Zeder 2012). Different pathways are possible for species that underwent multiple domestications, such as pigs (see PIGS). Alternatively, animals could be grouped according to the purpose of domestication, whether for animal products—such as meat, milk/blood, hide/fur/feathers—or for transportation and traction. The different ways in which animals are managed have implications for gene flow and the emergence of domestication traits.

Domestication and early agriculture

Evolutionary perspectives focus upon the directionality and fixation of phenotypic traits, as well as genetic correlates during domestication. Yet, questions remain in terms of clarifying precisely when domestication was initiated and when it ended. Rather than viewing species as having two forms—“domestic” and “wild”—for many species

Table 1 Comparison of domestication traits in sexually reproduced plants (including cereals and legumes) and vegetatively propagated plants (including root crops, sugarcane, and bananas).

<i>Trait</i>	<i>Domestication in sexually reproducing plants</i>	<i>Domestication in asexually reproducing plants</i>
Size of edible portion	Increased seed size in cereals, legumes, nuts	Increased size of edible portion, most marked in starch-rich plants
Ease of harvesting	Development of nonshattering seeds	Decreased seed size/suppression in some fruits
Timing of fruit production	Synchronous food production within plant and between plants of the same species	Potential development of bunching equivalent
Plant architecture	Apical dominance	Asynchronous and more continuous food production, with in-ground storage for some root crops
Plant life cycle	Shift towards annual life cycle based on sexual reproduction from seed	Apical dominance in some plants Shift towards perennial life cycle based on vegetative production of suckers, shoots, subterranean storage organs, and other viable plant parts
Photoperiod sensitivity	Loss of photoperiod sensitivity	Uncertain change to photoperiod sensitivity
Defensive adaptations	Loss of defensive adaptations (spines, hard seed casings, toxicity, acidity) to enhance harvesting, processing, and consumption Easily adapted to new environments	Loss of defensive adaptations (spines, hard seed casings, toxicity, acidity) to enhance harvesting, processing, and consumption Triploidy and vegetative propagation enable cultivation in wider environmental (altitudinal and latitudinal) ranges
Environmental tolerance		
Disease resistance	Reduced resistance to disease and pests due to human selection following continued sexual reproduction of subpopulation	Dramatic reduction in resistance to disease and pests due to low genetic variability in clonally reproduced cultivars
Palatability	Increased selection for desired traits	Increased selection for desired traits

Table 2 Domestication pathways for animals.

Pathway	Description	Examples
Commensal	Animals became habituated to people and the human niche, such as settlements, and gradually became embroiled in domesticatory relationships with people	Dog (<i>Canis familiaris</i>) Cat (<i>Felis catus</i>) Pig (<i>Sus scrofa</i>) Chicken (<i>Gallus gallus</i>) Ducks (Anatidae) Turkey (<i>Meleagris gallopavo</i>)
Directed	People used preexisting knowledge and practical experience of managing and herding animals to directly domesticate a species for a specific purpose or resource	Horse (<i>Equus caballus</i>) Donkey (<i>Equus asinus</i>) Camel (<i>Camelus</i> spp.)
Prey	Animals were originally hunted for hide, bone, and meat; people gradually began to manage animal populations to maintain hunting levels, which eventually led to more direct rearing and herding	Goat (<i>Capra hircus</i>) Sheep (<i>Ovis aries</i>) Cattle (<i>Bos taurus</i>) Pig (<i>Sus scrofa</i>)

Source: After Zeder 2012.

there is a continuum including “semidomesticated” and “domestication gradients.” To date, there has been an overemphasis on the evolutionary aspects of the domestication process in archaeology, with an underappreciation of environmental controls on genetic expression, such as epigenetics and plasticity (Larson et al. 2014).

In recent years, the number of “centers” of early domestication and agriculture has increased (Larson et al. 2014). This has led some to advocate a more decentered approach that focuses on the domesticatory relationships between people and other species in place and time. The presence or frequency of domesticates has been used to identify agriculture in the past, whereas more recent definitions shift to a reliance on the cultivation of plants and the husbandry of animals for subsistence to identify agriculture in the past. The conceptual shift is twofold: socially, the dependence of people on cultivated foods and managed animals is manifest in the ways they structure their lives and society; and, biologically, the emergence of domestication traits in animals and plants is influenced by a range of social and environmental factors.

Domestication of Equids

ROBIN BENDREY

University of Edinburgh, UK

The domestication of two equids—the horse and the donkey—enabled profound and lasting changes to human societies and economies. The use of these animals to aid transportation sustained larger interacting communities and enabled people, possessions, ideas, and diseases to circulate faster and more efficiently. An important factor in the development of mobile pastoralism on the Eurasian steppe, domestic horses (*Equus caballus*) were probably also pivotal in large-scale ancient migrations westward influencing the genetics and languages of Europeans until today. Likewise, domestic donkeys (*Equus asinus*) had an important role in the organization of early states and pastoral societies in North Africa and the Near East.

Current understanding views the earliest animal domestications as emerging unintentionally along gradual coevolutionary pathways, with later domestications often seen as more rapid products of deliberate human selection, in that once agriculture had emerged and spread, human communities were able to envisage other wild species as potentially desirable resources through domestication. Both horse and donkey are normally viewed as belonging to the latter category, emerging as domesticates in the mid-Holocene, although the process may have been slower and less linear than previously thought (Rossel et al. 2008).

Both horse and donkey domestications have been highly debated and controversial topics, in part because of the scientific challenges in identifying the early stages of domestication and the degree of coverage of archaeological research in the relevant regions. Although tensions still exist between different strands of evidence, multidisciplinary research is providing increasingly robust and detailed reconstructions. Animal domestications are investigated

through a range of techniques, especially the analysis of archaeological sites and finds, animal remains (zooarchaeology), and the genetics of both modern and ancient livestock.

Horse domestication

Horses are adapted to open grasslands with relatively poor habitat quality and strong seasonal variations in climate. They can tolerate cold, dry weather and also continue to feed during winters with deep snow. Around the time of domestication, the distribution of wild horse (*Equus ferus*) populations is thought to correlate with the distribution of open environments along the Eurasian steppes. Their main distribution was limited to the west by the more closed, wooded environments of Europe, and to the south by generally hotter and drier environments, although limited numbers of wild horses, likely relics of the Pleistocene distribution, did occur in small and sparse populations into the earlier Holocene in some areas of Europe and the Near East.

Wild horses were a common prey of hunter-fisher-gatherer communities along the Eurasian steppes. It is within this region that horse husbandry first emerged in the mid-Holocene. The Eneolithic Botai culture of northern Kazakhstan (ca. 3600–3100 BCE) has produced the earliest evidence for domestic horses from a series of substantial sites with high proportions of horse remains. Key evidence includes lipid residues from pottery indicative of horse milk, wear traces on horse teeth linked to harnessing, changes in the morphology of the bones, and probable corrals and use of horse manure (Olsen 2006; Outram et al. 2009). This indicates the multipurpose use of horses, for transport, meat, milk, and manure. The initial goals behind horse domestication are still debated; however, what is clear is that this earliest known horse husbandry is in a context where it was by far the dominant food animal, and horses' adaptation to the steppe region would have made them an ideal managed food source. The apparent absence of other domestic livestock from the

steppes of northern Kazakhstan at this time raises the possibility of horse domestication being an independent, indigenous innovation (Outram et al. 2009). A study of ancient DNA further indicates horse domestication on the Eurasian steppes prior to 3000 BCE (Ludwig et al. 2009). This identified a rapid and substantial increase in the number of coat colorations around this time, which is best explained by selective breeding after domestication. There is also the possibility of another domestication center on the Iberian Peninsula indicated by a combination of zooarchaeological and genetic data; however, whether this represents an independent event from the domestication on the Eurasian steppes, or simply the introgression of local wild stock into introduced domestic herds, is currently uncertain.

Genetic studies provide insights into the processes surrounding the origins and geographical diffusion of horse husbandry. Modeling of genetic data collected from modern nonbreed (local village) horses throughout northern Eurasia has identified domestication origins in the western Eurasian steppe, along with significant introgression from wild populations as horse husbandry spread (Warmuth et al. 2012). Further, modern populations of domestic horses demonstrate considerable mitochondrial DNA (mtDNA) variability (relating to maternal lineages) and extremely low nucleotide diversity on the Y-chromosome (relating to paternal lineages). This suggests the frequent incorporation of wild mares into domestic herds as horse husbandry spread; but not stallions, probably because they are less manageable. There is considerable diversity on the male-inherited Y-chromosome in samples from pre-domestic wild horses, indicating that reproduction from a limited number of stallions is related to the domestication process (Lippold et al. 2011).

Donkey domestication

African wild asses (*Equus africanus*) are adapted to arid and semi-arid environments, with physiological tolerance to limited water. They live in low densities and exhibit low sociability, both factors potentially linked with forage availability. Skeletal finds indicate that African wild asses were

occasionally hunted across northeastern Africa from around 20,000 years ago. This distribution extended across the Sahara and into northwest Africa until Roman times, and possibly into the Arabian Peninsula and the Levant (although the latter is uncertain; Marshall 2007). There are currently two recognized subspecies: the Somali wild ass (*E. a. somaliensis*) is critically endangered and is found in Somalia, Ethiopia, and Eritrea; and the Nubian wild ass (*E. a. africanus*) may now be extinct in the wild, but was found in northern Sudan and Eritrea (Kimura et al. 2013).

The earliest archaeological evidence for domestic donkeys comes from pre-dynastic Egypt. Body size decreases, interpreted as evidence for domestication, are recorded at the sites of El Omari (ca. 4800–4500 BCE) and Maadi (ca. 4000–3500 BCE) (Kimura et al. 2013). However, size decrease has been shown to be a relatively late indicator of donkey domestication (Rossel et al. 2008). The earliest evidence for transport use comes from ten articulated skeletons with paleopathologies indicative of overloading and strain found at Abydos (ca. 3000 BCE) adjacent to the mortuary complex of one of the founder dynasty Egyptian kings (Rossel et al. 2008). The elite context clearly demonstrates the cultural significance of these animals.

Genetic data from modern domestic donkeys identify two distinct mtDNA groups (clades 1 and 2), indicating their domestication from two separate wild populations. The Nubian wild ass has been identified as the ancestor of clade 1 donkeys; the geographical origins of clade 2 donkeys could include northeast Africa, the Maghreb of northwest Africa, and Yemen on the Arabian Peninsula (Kimura et al. 2010). A recent study by Rosenbom et al. (2015) assessed levels and patterns of genetic variation from different hypothesized areas of donkey domestication, with centers of origin being expected to retain more ancestral variation. They identified two areas as possessing the highest genetic diversity values: results from Sudan confirm the conclusions already reached by the mtDNA analyses; results from Yemen suggest another possible domestication event. The early presence of African wild ass or early domestic donkeys at Ash-Shumah (Yemen) during the mid-seventh millennium BCE further supports this potential (Marshall 2007).

A range of evidence, in addition to delayed body size change, indicates that donkey domestication was slow and complex. Genetic studies indicate Nubian wild asses sharing haplotypes with clade 1 domestic animals, possibly representing protracted and multiple recruitments of wild individuals, whereas the clade 2 network suggests a more restricted domestication event, involving a limited number of animals (Kimura et al. 2010; 2013). Ethnographic evidence indicates donkeys in Africa and Asia are rarely intentionally bred, due to a combination of wild ass behavior and human management strategies, although the practice of breeding domestic donkeys with wild asses in the early phase of domestication would explain the observed evidence (Marshall 2007; Kimura et al. 2013).

The integration of archaeological and genetic evidence indicates at least one domestication event in northeast Africa ca. 6,000–5,000 years ago. This occurred after cattle-based pastoralism had spread through the region. The subsequent retreat of the monsoonal rain front led to desiccation and desertification of the Sahara, forcing pastoral range changes and greater mobility. In these conditions, African wild asses clearly had advantages over cattle as domesticates for transport (Marshall 2007). The low number of early domestic donkeys at archaeological sites indicates they were not a primary food resource. The increasing aridity and the spatial distributions of cattle pastoralists and wild ass populations in northeast Africa present the likely context for domestication by mobile pastoral communities, rather than in the Egyptian Nile Valley (Marshall 2007).

Future directions

The complexities and challenges of studying domestication demonstrate the need to approach this through multiple, integrated techniques, as single methods offer overly simplified and biased views of the past. Methods that can give insights into subtly changing ecology, diet, and management, such as paleopathology and stable isotope analysis, deserve greater attention. Rapid advances have been made in recent years in the population genetics of domestic equids, and integrated archaeological approaches exploring

changes through time and space need to keep pace with these. For horses, for example, archaeological work is necessary to investigate whether horse husbandry in the Botai culture emerged abruptly or gradually from a local trajectory of intensifying horse management, whether it emerged earlier elsewhere, and whether or not any existing practice or knowledge of animal husbandry stimulated this transition in its emergent context. For donkeys, similar focus should be directed at those areas likely to have witnessed intensifying contact between ancient Saharan pastoralists and African wild ass populations during the desertification of the Sahara.

SCOTT M. FITZPATRICK

University of Oregon, USA

Theory

Biochemical mechanisms of plants and fungi generate a wide diversity of secondary metabolites that appear to have either adaptive or neutral survival value in the ecosystems in which these species have evolved. A large number of these natural compounds have mild to profound effects within the central nervous systems of *Homo sapiens*, and people have discovered many of their psychoactive effects empirically over millennia of interaction (e.g., see Schultes, Hofmann, and Rätsch 2002 for an extensive list of traditional human–psychoactive drug plant associations).

From ancient times, plant and fungi sources of bioactive substances have been used to heal or provide support in daily work, as well as to escape from life's harsh realities and inspire the ritualized development of spiritual beliefs. Indeed, there are a relatively large number of psychoactive drug plants and fungi that appear to have had ancient mind-altering relationships with humans. Many of these have been documented in the archaeological record from numerous parts of the world, although the degree of archaeological evidence supporting these prehistoric and historic relationships varies significantly.

How and why have humans developed long-term relationships with these kinds of species? In many modern societies, people generally dismiss “divine visions” as hallucinations that are unreal, and the yearning to experience a direct communication with a supernatural force is frequently construed as an indication of mental disorder. Nevertheless, some scholars and scientists assert that such visions and communications are fundamentally associated with an

ancient and ongoing pan-global cultural tradition involving the use of mind-altering experiences to produce profound, more or less spiritual and cultural understanding (e.g., see Bourguignon 1973; Schultes et al. 2002; Merlin 2003; Clarke and Merlin 2013). This enduring human connection with various psychoactive plants and fungi is a relationship of great antiquity. It may have even originated before the evolution of our own genus, but almost certainly within the temporal span of our own species dating back into the Pleistocene.

A fundamental model of how and why humans have long used psychoactive plant or fungi materials for spiritual reasons was well articulated half a century ago, when anthropologist Weston La Barre responded to a rhetorical question posed to him by the Harvard ethnobotanist Richard Evans Schultes. Within his response, the Duke anthropologist La Barre (1970) contended that people, at least in polytheistic contexts, have been “culturally programmed” to find plants (or fungi) that facilitate communication cognitively with their spirit world. La Barre suggested that this custom had its origins in the Paleolithic Era, well before the rise of cultivation, when all humans were hunters and gatherers. According to his proposition, as bands of humans dispersed into new regions, including new ecosystems, they brought with them a culturally inspired motivation to identify and utilize species of plants or fungi that would allow them to transcend their “normal” perceptions and empower them to communicate with their ancestors or deities.

In modern societies, psychoactive materials are used in a variety of ways. These include religious, medical, and secular applications, which in ancient times may or may not have been viewed as separate. For example, in the case of Neolithic Europe, some have argued that psychoactive substances were often consumed in a spiritual context, which would have included therapeutic uses too, because it would have been artificial to separate bodily healing from ritualistic observance. However, it has also been suggested that evidence for the consumption of mind-altering substances in the past,

such as THC-rich cannabis or morphine-laden opium, should not necessarily be interpreted as a manifestation of either deep ritual importance or utilization for largely pleasure-seeking purposes; such drugs “may simply belong to the material medica” (Sherratt 1995). For example, small opium poppy fruit capsules dated to the early Neolithic, which were placed in small woven bags and set next to human bodies in a burial cave in southern Spain, most likely were put there because of their pain-alleviating potential and/or as a source of psychoactive power to help the deceased’s progress to an afterlife (e.g., see Becerra Romera 2006; Gavilán Ceballos 2008).

In any case, under diverse conditions of non-industrial societies, psychoactive substances were apparently often used in ritualistic, religious contexts; for whatever purposes, the widespread ancient human use of mind-altering species has been documented archaeologically (e.g., see Merlin 2003; Clarke and Merlin 2013). It is also essential to remember that ingestion of psychoactive substances can produce a variable altered state of consciousness depending upon the quality and quantity of the mind-altering compounds eaten or imbibed, the psychological set of the user, and the social–environmental setting in which the substance is consumed.

Methodology

Data used to support the widespread ancient use of psychoactive drug species can be found in the literature across various disciplines, such as anthropology, archaeology, paleoethnobotany, palynology, ethnobotany, and history. Dating of evidence varies in technique and relative reliability depending on the type and quality of the specimen. Most samples, because of their organic nature (e.g., seeds, charcoal, fibers), have been dated using the radiocarbon method (e.g., El-Seedi et al. 2005), while others such as pottery can be dated using luminescence techniques (Fitzpatrick et al. 2009; see DATING CERAMICS AND LUMINESCENCE). Other chronological documentation has relied on reference to the written record, sometimes in conjunction with iconography. The archaeological evidence for psychoactive drug plant research has traditionally come in two

forms: artifacts and plant remains. The advantages and disadvantages of both forms of evidence must be considered.

All artifacts are subject to some type of interpretation and reconstruction. Differences in interpretation may arise concerning the specific identification of the organism that the artifact is supposed to represent, its association with other archaeological remains, and interpretation of its artistic, religious, medicinal or other practical or psychological uses. The paleoethnobotanical record (see PALEOETHNOBOTANY) is usually much less subjective. However, difficulties in assigning specimens to specific taxa may occur, and confirmation of its alleged use by humans is also sometimes difficult or even contentious, particularly if the context in which the remains are found is unclear. The most dependable information should be a supportive combination of the two types of archaeological evidence. Although ideally scholars should identify the symbolic meanings intended in species depictions manifested in artifacts, along with their microfossil or macrofossil presence in related archaeological sediments, the discovery of this type of corroborative evidence has been rare. Much of what is known from Europe is paleoethnobotanical, while in other areas such as the Near East and East Asia, the evidence, at least until recently, has usually been limited to artifacts and interpreting their function and meaning. This reflects the focus, history, and relative technological sophistication of research undertaken by archaeologists working in these respective areas.

Artifact interpretation may vary between different schools of archaeological theory, or simply may differ in the identification of what species is represented. For example, an evolutionary theorist may be hard-pressed to refer to a clay figurine as a religious object because it appears to have enormous breasts and hips; or artifacts depicting globular “fruit” may seem to some to be representations of opium poppy (*Papaver somniferum* L.) capsules, but to others they look like depictions of pomegranate (*Punica granatum* L.) fruits (Merlin 1984). However, any interpretation without convincing supportive evidence may be premature or inaccurate. Documentary evidence is usually not available. Therefore, a prudent interpretation of archaeological remains must

take into account the context and associations of the artifact within the site.

Paleoethnobotany is a subfield that seeks to explain human–plant relations over time through the identification and analysis of archaeological plant remains. Historically, some macroscopic plant remains that were discovered and removed from ancient sites in the early stages of archaeological research were not appropriately extracted from undisturbed (in situ) contexts; for example, a series of ancient opium poppy (*P. somniferum* L.) capsules (referred to above) found in southern Spain, and many ancient opium poppy seeds from various central European sites, were not recovered from well-sealed closely dated deposits (Merlin 1984). While these remains can normally be dated as precisely as possible, accurate determination of their prehistoric contexts is often disputable; nevertheless, they are currently still some of the most direct early evidence of the presence and probable use of this species in the region (also see Jiang et al. 2006 for recent remarkable discoveries of ancient *Cannabis* remains associated with humans).

Future Research

Albeit still somewhat fragmentary, the archaeological and paleoethnobotanical records, along with evidence from “historical contextualization”, offer broadly-based geographical and ethnobotanical confirmation for a very widespread, deep time model of human use of psychoactive substances. Precisely when people initially decided to consume a psychoactive substance will most likely remain unknown due to the vagaries of preservation of artifacts and especially organic materials. Nevertheless, archaeologists now have the unique opportunity to extract more information from ancient subfossil and fossil remains; the antiquity of such remains may date back hundreds or even thousands of years in contexts that can offer more meaningful interpretations of their ancient relationships with people. The expertise of scientific recovery, identification and analysis of ancient mind-altering substances, and the paraphernalia used to ingest them, has improved dramatically in recent years. This exponential increase in data recovery and informed interpretation has been facilitated by improved techniques

in various natural science disciplines, as well as archaeology. Archaeologists and paleoethnobotanists can now better document and explain depositional stratigraphy, clarify the composition and utility of artifacts, more accurately identify micro- and macrobotanical remains, and describe and interpret ancient environmental parameters and human skeletal remains with greater methodological and theoretical sophistication. Using powerful tools of modern science and human imagination, along with remaining ethnohistorical explanations and ethnographic accounts, our understanding of humans’ deep-rooted desire to experience “ecstasy” in the original sense of the word (to break the mind free from the body and communicate with the “gods” or the ancestors) is becoming stronger over time.

Environmental Archaeology

GILL CAMPBELL
Historic England, UK

Introduction

Environmental archaeology is the study of people and their interaction with the environment over time. It involves the application of the natural and physical sciences to the study of biological remains and to the deposits in which they are preserved, for the purpose of understanding how people both shaped and were shaped by their environment over millennia. Environmental archaeologists are concerned with how people obtained the necessities of life—food, drink, warmth, and shelter—and how, in doing so, they altered the world around them; these are often referred to as paleoeconomic questions. At the same time, they are interested in how the environment has changed over time through natural and human induced climate change and how plants and animals have adapted and evolved as a result of these changes, often referred to as paleoecological questions. They are also concerned with human behavior, especially how people related to, and perceived, landscapes and living things through space and time.

Key areas of interest include processes of domestication (see DOMESTICATION) and the development of farming; the use of natural resources in craft and industry (for example, metal production and working, and pollution arising from these activities; the creation of cultural landscapes and novel environments (see URBAN ENVIRONMENTS); the role of animals and plants in ritual and belief; how humans respond to environmental changes such as sea-level change and natural disasters. The study of people themselves—especially diet, health, and disease—and geoarchaeology are included within the scope of environmental archaeology, though some regard these as somewhat separate

disciplines. However, the approach taken here is a holistic one, which regards humans and their culture and behaviors as part and parcel of the ecosystems they inhabit (Evans and O'Connor 1999, 1; Butzer 1982).

Preservation and recovery

Fundamental to environmental archaeological research is an understanding of taphonomy and formation processes, from the microenvironment of an artifact, archaeological context, or deposit to processes operating at the scale of an individual site, of a region, or even globally. In order to establish what kinds of research are possible, environmental archaeologists need to know what types of biological remains are likely to be present in a particular location, how these remains are likely to be preserved, and how they entered the deposit. Taking a different approach, they may start with a research question or hypothesis and then target those sites and environmental evidence that can best answer the question posed.

Paleoenvironmental questions are best addressed through the investigation of naturally accumulating deposits, where direct human input is limited. Such deposits are often called paleoenvironmental archives, and the investigations carried out on them are known as off-site or paleoecological studies. However, even within seemingly natural or pristine environments, humans will almost certainly have been operating in the past. For example, lakes will have been fished and will have supplied drinking water for people and animals. Occupation is likely to have occurred at the lake edge and on islands within the lake. People may even have constructed artificial islands or platforms within the lake itself. It is vital that these possibilities are considered when undertaking work at such sites, so that the influence of these activities can be taken into account as part of any investigation.

Where the principal aim of the research is to answer paleoeconomic questions or to explore social relationships with plants and animals, on-site studies are usually preferred. Ideally

the types of deposit chosen are those that both formed and were sealed rapidly and where there is little or no evidence for intrusive or residual material, for example, a pit that was dug, filled up with rubbish from activities happening nearby, and then sealed. However, the suitability of the context will depend on the types of question posed as well as on the nature of the archaeological record at that time and location. What is vital, however, in both on-site and off-site studies, is an understanding of how the various types of material ended up in the deposit and what happened to them after they entered it.

A key distinction here is between material that formed in situ and lived in the deposit (the structure itself and the organisms living on it or in it) and material that entered the deposit or structure from the outside, either as a result of natural processes such as wind and rain or as a result of human agency, which may be deliberate or incidental. The former kind of remains are referred to as *autochthonous* (from the ancient Greek adjective *autochthonos* “from the same land,” itself a compound of *autos* “same” and *chthōn* “earth, land, territory”)—for example, seeds from plants that grow on the surface of a deposit, or insects living in a building; the latter kind of remains are referred to as *allochthonous* (from the ancient Greek adjective *allochthonos* “from another land, foreign,” a compound of *chthōn* with *allos* “other, different”). *Allochthonous* material includes for example, seeds washed or blown in from the surrounding area, plant “waste” from crop processing disposed of in a pit (deliberate deposition), or seeds that end up in a cesspit having survived passage through the human gut (incidental deposition). The ways in which *allochthonous* material may enter a deposit are myriad. In addition, such material may be derived from a variety of sources, either close to the point of deposition or at a considerable distance from it. Material of different ages may also end up in the same deposit, for example, wood used on a fire might contain wood from a demolished structure of considerable age, driftwood may be collected from the shore along with kindling from local heathland collected earlier that week. Disentangling these formation processes is an essential part of analysis and interpretation.

Another important factor is knowledge of what has been lost because it failed to be preserved.

Broadly speaking, permafrost conditions, very arid conditions, and conditions of oxygen depletion (anoxic or anaerobic deposits) result in the excellent preservation of a wide range of biological remains over thousands of years. Outside these extremes, the preservation of biological remains is influenced by the pH of the deposits, the depth of the burial, temperature, and fluctuations in moisture content. For example, animal bone and mollusks survive well in oxic deposits where the pH is > 7.0 , whereas pollen will not survive. In contrast, in oxic deposits where the pH is < 5.5 , bone—unless calcined as a result of burning—will not be preserved, whereas pollen will be well preserved (Campbell, Moffett, and Straker 2011, fig. 1; Evans and O'Connor 1999, 80–81). Plant remains preserved by charring (carbonization), wood charcoal included, will survive well in most deposits, unless subject to mechanical weathering such as repeated wetting and drying or freeze–thaw processes (Miksicek 1987).

In addition to considering whether broad categories of remains will be preserved at a site, the differential preservation of different parts of organisms or between different organisms needs to be taken into account. For example, where crops such as cereal crops are exposed to fire as part of being processed into food for humans, they will have a greater chance of being preserved by charring and of becoming part of the paleoethnobotanical record. By contrast, remains of leafy vegetables will be preserved relatively rarely, for instance, through desiccation, or as a result of anoxic conditions; and even then it may be difficult to distinguish them from other plant leaves (van der Veen 2007). In some contexts preservation conditions may be such that only more robust remains are preserved. For example, pollen from lime trees (*Tilia* sp.) will survive much better than pollen from beech trees (*Fagus* sp.), while fern (Pteropsida) spores are particularly resistant to decay (Wilkinson and Stevens 2003, 94; Bunting and Tipping 2000). For these reasons, it is necessary to carry out preservation or condition assessments in order to determine the extent of postdepositional bias for a given assemblage (Bunting and Tipping 2000).

Processes of excavation, sampling, and recovery will also influence the nature of assemblages. Oyster (*Ostrea* sp) shells generally survive

excavation more or less intact, while shells of the common mussel (*Mytilus edulis*), preserved whole in the ground, will break up on excavation because the parts of the shell are very fragile (Winder 1980). Charcoal will further fragment, if wet sieved or floated. The elements and range of species of animal bone recovered will depend on the minimum mesh size used when sieving samples (Baker and Worley 2014, figure 7).

A useful way to approach the recording of preservation and taphonomic evidence is to run the taphonomic trajectory in reverse, starting with the assemblage as observed in the laboratory and considering how the observations made relate to the effects of excavation and recovery strategies, the processes that occurred after deposition (burial), and the processes that took place between the death of the organism and its burial, including cultural processes. Once these effects are accounted for, the environmental archaeologist will have a much better understanding of the original living organism or group of organisms that the assemblage s/he is studying represents (O'Connor in Baker and Worley 2014, 27–8).

Identification and interpretation

An accurate determination of the biological remains to the lowest possible taxonomic level—be that variety, subspecies, species, genus, or family—is fundamental to the practice of environmental archaeology. To identify their material, environmental archaeologists use a combination of identification guides and modern comparative references collections, along with published identification criteria developed for particular classes of remains. In doing so, they accept the premise that species living today are analogous to those that were living hundreds or thousands of years ago and that they have had similar physiological requirements to those of the species alive today—notwithstanding that processes of change such as those that occur as a result of domestication and the introduction of new species into novel environments are the very topics that the discipline seeks to investigate. Hence whether a living species can be regarded as the equivalent of a species with the same characteristics recovered from deposits thousands of years old is one of the

hypotheses that needs to be tested as part of the research process (Dincauze 2000, 29).

Related to this concept of analogical reasoning is the principle of uniformitarianism, often summed up by the phrase “the present is the key to the past.” This idea was first postulated by the geologist James Hutton and further developed by Sir Charles Lyell. The core of this principle is that the natural processes that take place on earth today are the same as those that operated in the past and produce the same effects. Thus sequences of deposits that characterize meandering rivers today will have the same characteristics and will have formed as a result of the same processes as deposits observed within the geological and geoarchaeological record. Although it is now recognized that natural processes that occur in the present are not directly equivalent to those that operated in the past, especially in terms of scale or duration, and that some environments that existed in the past do not exist today, this concept, modified to take account of these observations and termed *methodological uniformitarianism* by Stephen J. Gould, remains central to paleoenvironmental reconstruction (Dincauze 2000, 30; Wilkinson and Stevens 2003, 28–31).

A natural consequence of this way of thinking is the idea that organisms can be used as proxies for the environments in which they occur. Thus, if bones of reindeer and woolly mammoth are recovered from a deposit currently within a temperate environment, the existence of cold-climate conditions at the time when the deposit was forming can be inferred (Dincauze 2000, 30). Some species have very precise requirements; for example, some parasites need specific hosts in order to complete their life cycle, while some insects will only feed on a single plant species. Such species are termed “indicator species,” since they show the presence of the plants on which they feed or animals they infect. However, in many cases, an indicator species, although typical of a particular habitat, will also be found in similar places, tolerating a range of environmental conditions. In addition, some species may have lived in environments that existed in the past but for which there is no modern equivalent.

An example of this is the seaweed fly (*Thoracochaeta zosterae*). This fly is currently found only along the marine shoreline within decomposing seaweed. However, its puparia are frequently
